Abstract

We study the problem of general entanglement purification protocols. Suppose Alice and Bob share a bipartite state ρ which is “reasonably close” to perfect EPR pairs. The only information Alice and Bob possess is a lower bound on the fidelity of ρ and a maximally entangled state. They wish to “purify” ρ using local operations and classical communication and create a state that is arbitrarily close to EPR pairs. We prove that on average, Alice and Bob cannot increase the fidelity of the input state significantly. We also construct protocols that may fail with a small probability, and otherwise will output states arbitrarily close to EPR pairs with very high probability. Our constructions are efficient, i.e., they can be implemented by polynomial-size quantum circuits.

1 Introduction

Random bits are an important computational resource in the randomized computation. There has been a lot of work on extracting good random bits from imperfect sources of randomness. The beginning of this study goes back to at least von Neumann [vN51] who showed that a linear number of perfect random bits can be extracted from independent tosses of a biased coin. More recent research has constructed extractors [NT99, T99] which can extract almost perfect random bits from any source with a certain min-entropy without any other assumptions. The best constructions of extractors allow to extract a number of random bits close to the min-entropy of the random source with min-entropy if we can use a polylogarithmic number of perfect random bits [TUZ01].

Quantum entanglement is an important resource in quantum computation, similar to random bits in probabilistic computation. It comes in the form of Einstein-Podolsky-Rosen pairs. An EPR pair is the state of two quantum bits $\frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$ shared by two parties, with one party (Alice) holding one quantum bit and the other party (Bob) holding the second bit. This is the quantum counterpart of a random bit shared by two parties.

Einstein-Podolsky-Rosen[EPR35] (EPR) pairs are among the most interesting objects of study in quantum mechanics and quantum information theory. They behave very differently from classical random bits shared by two parties. The phenomenon of having *entangled* states separated by space is one of the quintessential features in quantum mechanics and it has no analogue in classical physics.

Besides being conceptually interesting in quantum mechanics, EPR pairs are also very useful in quantum information theory. Using an EPR pair, Alice and Bob can perform quantum teleportation. Using only local operations and classical communication (LOCC), Alice can “transport” a qubit to Bob,

*Supported by NSF Grant CCR-9987845 and the State of New Jersey.

†A preliminary version of this paper is submitted to STOC 2002

who could be miles away from Alice [BBC+93]. So EPR pairs, along with a classical communication channel, effectively constitute a quantum channel. Conversely, “superdense coding” is possible with EPR pairs: if Alice and Bob share an EPR pair, then Alice can transport 2 classical bits to Bob by just sending one qubit [BW92].

For the teleportation and dense coding to work perfectly, perfect EPR pairs are needed. Nevertheless, individual qubits are prone to errors, which may end up creating imperfect EPR pairs. These imperfect EPR pairs behave like a noisy channel — qubits teleported with these EPR pairs can become distorted.

This creates the need for generating perfect (or almost perfect) EPR pairs from imperfect ones. This is known as “entanglement purification”. Bennett et. al. [BBP+96a] gave a protocol for the case that Alice and Bob share identical copies of the pure state $|\phi\rangle = (\cos\theta|01\rangle + \sin\theta|10\rangle)$. This was extended to the case when Alice and Bob share identical copies of a mixed state [BBP+96b, BDS+96, HHH96]. Vidal [V99], and subsequently, Jonathan and Plenio [JP99], Hardy [H99], and Vidal, Jonathan, and Nielsen [VJN00] considered extracting entanglement from a single copy of an arbitrary pure state, assuming that we know a complete description of the state.

All of this work uses relatively simple models for imperfect EPR pairs. The model where Alice and Bob share identical copies of the same state corresponds to generating perfect random bits from the sequence of i.i.d. biased coin flips. Extracting entanglement from a single copy of a known state corresponds to constructing uniform/almost uniform random bits from a biased distribution if we know a complete description of the distribution. Both of those are very easy tasks classically but dealing with quantum states makes them much harder.

Can we extract entanglement if we do not have such a detailed knowledge of the quantum state (like extractors in the classical setting which work for any probability distribution satisfying certain constraints)? This is the question that we consider in this paper.

1.1 Our error model

We no longer assume that there is a single “distortion” operator that acts independently on each qubit pair, neither do we assume that Alice and Bob have complete information about the distortion. The only assumption that we have is that the distortion is not very large. More precisely, we assume that Alice and Bob share a state ρ with fidelity at least $(1 - \epsilon)^1$. We call this model of imperfect EPR pairs the “General Error” model. We call the protocols for this model General Entanglement Purification Protocols (GEPPs).

In the General Error model, the techniques used in previous literature don’t appear to work. Some of the techniques rely on the Law of Large Number heavily. For example, both the “Schmidt projection” method [BBP+96a] and the “hashing” method [BDS+96] try to reduce the state to a “typical sequence”, and then do purification over the typical sequences. In the General Error model, it is not clear what a “typical sequence” would be. Some techniques, like the “Procrustean” method [BBP+96a], are designed to work with individual states that Alice and Bob have complete knowledge of. Apparently they don’t work in the General Error model, where Alice and Bob only have very limited information about the state they share. In fact it is not obvious if Alice and Bob can do anything at all to extract EPR pairs in this model.

1.2 Our Contribution

Some features about GEPPs are:

1. Arbitrary Maximally Entangled States

Instead of working only with EPR pairs, a GEPP works with arbitrary maximally entangled states. In every symmetric bipartite system of dimension $T \times T$, there exist a maximally entangled state $\Psi_T = \frac{1}{\sqrt{T}} \sum_{i=0}^{T-1} |i\rangle^A |i\rangle^B$. In the case that T is a power of 2, Ψ_T is the state of $\log_2 T$ EPR pairs.

¹Most of the time in this paper, we are interested in the fidelity of a state ρ and a (pre-defined) maximally entangled state (e.g., an EPR pair). In this case, we simply use the “fidelity of state ρ ” to denote the fidelity of ρ and the pre-defined maximally entangled state of appropriate dimension.

Thus, extracting EPR pairs is a particular case of our setting. We note that, by a result of Nielsen [N99], Alice and Bob can transform Ψ_N into Ψ_M for any $M < N$. Therefore, if we want the final state to be a set of EPR pairs, we can just add a step at the end of protocol that maps Ψ_N to $\Psi_{2^{\lfloor \log N \rfloor}}$ and obtain a state of $\lfloor \log_2 N \rfloor$ EPR pairs.

2. Auxiliary Input

Besides an input state ρ , a GEPP also has a maximally entangled state Ψ_K as auxiliary input. This assumption is similar to having extra perfect random bits in randomness extractors.

3. Possibility to Fail

We allow a GEPP to fail with a reasonably low probability. As we will prove later, a GEPP that never fails won't be able to increase the fidelity of the input state significantly, even if it has an extra input Ψ_K . However, if we allow a GEPP to fail, then in the case that it doesn't fail, it will be able to output states of very high fidelity with very high probability. In general, a GEPP will either output a special symbol **FAIL** or output a state, which has (hopefully) very high fidelity.

We consider 3 types of GEPPs. Roughly speaking, we say a GEPP is *absolutely successful*, if it never fails, and always outputs a state of very high fidelity. We say a GEPP is *deterministically conditional successful*, if the probability it fails is small, and when it doesn't fail, it will output a state of very high fidelity with certainty. We say a GEPP is *probabilistically conditionally successful*, if the probability it fails is small, and in the case it doesn't fail, it outputs a state of very high fidelity with high probability. Each definition is a generalization of the previous one: an absolutely successful GEPP is deterministically conditionally successful, and a deterministically successful GEPP is probabilistically conditionally successful. We prove the following results:

1. There don't exist absolutely successful GEPPs with "interesting" parameters. To be more precise, we prove the following result: Suppose Alice and Bob share a state of fidelity $1 - \epsilon$, and they have an auxiliary input Ψ_K . They then perform LOCC to create a state σ in a subspace of dimension $M \times M$. Then the maximal fidelity Alice and Bob can guarantee about the state σ is at most $1 - \frac{N}{N-1}(1 - \frac{K}{M})\epsilon$. If K is significantly smaller than M improvement of fidelity is very small. In other words, Alice and Bob cannot arbitrarily increase the *average* fidelity of the input state.
2. There exist deterministically conditionally successful GEPPs for states in the diagonal subspace. A diagonal subspace is spanned by states of the form $\sum_i \alpha_i |i\rangle^A |i\rangle^B$. As we will show later, a state in the diagonal subspace is "easy" to work with and there exists an efficient protocol that is deterministically conditionally successful. For an input state of fidelity $1 - \epsilon$, the protocol will fail with probability at most ϵ , and when it doesn't fail, it always outputs a state of fidelity $1 - \frac{\epsilon}{L}$, where L is a parameter that can be made very large. We call our protocol the "Simple Scrambling protocol". The Simple Scrambling protocol is optimal in the sense that the average fidelity of its output matches the upper bound asymptotically.
3. There exist probabilistically conditionally successful GEPPs for arbitrary states. We present a protocol, namely the "Hash and Compare protocol". The Hash and Compare protocol converts an arbitrary state $|\phi\rangle$ of fidelity $1 - \epsilon$ to another state $|\phi'\rangle$ of fidelity at least $1 - \epsilon$, such that $|\phi'\rangle$ is "almost" in the diagonal subspace. Then the Simple Scrambling protocol can be used on state $|\phi'\rangle$ to create a state with very high fidelity.

Both the Simple Scrambling protocol and the Hash and Compare protocol are efficient, i.e., they can be implemented by polynomial-size quantum circuits. We present the precise definitions and results in the next section.

2 Notations and Definitions

2.1 General Notations

All logarithms are base-2. We use $[N]$ to denote the set $\{0, 1, \dots, N-1\}$. We identify an integer with its binary representation, and view its binary representation as a bit vector. The XOR of two integers x and y , denoted by $x \oplus y$, is the XOR of the two bit vectors x and y represent. The *inner product* of x and y , denoted by $x \bullet y$, is defined as the inner product in GF_2 of the two bit vectors x and y represent.

We study quantum systems of finite dimension. We identify a pure state (written in the “braket” notation as $|\phi\rangle$) with a (column) vector of unit length. We identify a mixed state with the density matrix of this state. For a quantum system whose states lie in the Hilbert space $\mathcal{H}$ of dimension N , we always assume that it has a canonical computational basis and we denote it by $\{|0\rangle, |1\rangle, \dots, |N-1\rangle\}$. Furthermore, we often denote $|0\rangle \in \mathcal{H}$ by $|Z_N\rangle$ to specify the dimension of this state.

We are mostly interested in *symmetric, bipartite quantum systems*, namely, systems shared between Alice and Bob, whose states lie in a Hilbert space $\mathcal{H} = \mathcal{H}^A \otimes \mathcal{H}^B$ and $\mathcal{H}^A \equiv \mathcal{H}^B$. Alice can access $\mathcal{H}^A$ and Bob can access $\mathcal{H}^B$. We always superscript subspaces and states to distinguish states accessible by Alice and Bob. For example, a general bipartite state $|\varphi\rangle$ can written in the following way:

$$|\varphi\rangle = \sum_{i,j} \alpha_{ij} |i\rangle^A |j\rangle^B$$

where $|i\rangle^A$ denotes the state of Alice and $|j\rangle^B$ denotes the state of of Bob. We sometimes subscript a space by its dimension. For example, $\mathcal{H}_N$ means a space of dimension N .

A quantum state is unentangled if it is of the form $|\psi\rangle^A \otimes |\psi'\rangle^B$. Any other pure state in $\mathcal{H}^A \otimes \mathcal{H}^B$ is *entangled*. For a pure state $|\varphi\rangle$ in a bipartite system, we define its *entanglement* to be the von Neumann entropy of the reduced sub-system of Bob when we trace out Alice:

$$E(|\varphi\rangle) = S(\text{Tr}_A(|\varphi\rangle\langle\varphi|)) \quad (1)$$

where $S(\rho) = -\text{Tr}(\rho \log \rho)$ is the von Neumann entropy. We have $S = 0$ if and only the state is unentangled. For mixed states, a mixed state ρ is unentangled if and only if it is equivalent to a state that is a mixture of pure states $|\varphi_i\rangle$ with probabilities p_i . Any other mixed state is entangled. However, there is no universally agreed definition for the amount of entanglement in a mixed state.

If we denote the dimension of $\mathcal{H}^A$ by N , then the maximum amount of entanglement in this system is $\log N$. We define the state Ψ_N to be

$$\Psi_N = \frac{1}{\sqrt{N}} \sum_{i=0}^{N-1} |i\rangle^A |i\rangle^B \quad (2)$$

It is a maximally entangled state in $\mathcal{H}^A \otimes \mathcal{H}^B$. Notice it is a state in a space of dimension N^2 . In particular, if N is a power of 2: $N = 2^n$, then the state Ψ_N is the state of n EPR pairs. We call this special kind of states *EPR states*.

2.2 Diagonal Subspaces

For a symmetric, bipartite system $\mathcal{H} = \mathcal{H}_N^A \otimes \mathcal{H}_N^B$, we denote by $\mathcal{H}^D$ the N -dimensional subspace spanned by

$$\left\{ \sum_{i=0}^{N-1} \alpha_i \cdot |i\rangle^A |i\rangle^B \right\}$$

and we call it the *diagonal subspace* of $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$. The reason for the name is: for a general state

$$|\varphi\rangle = \sum_{i,j} \alpha_{ij} |i\rangle^A |j\rangle^B$$

we can write its coefficients (totally N^2 of them) in a matrix form, where the (i, j) -th entry is $\alpha_{i,j}$, then the elements in $\mathcal{H}^D$ correspond to the diagonal matrices. Notice that this definition is also consistent with the “Bell-diagonal” [BDS+96] states for $N = 2$. A mixed state ρ is in the diagonal subspace, if there exists a decomposition of ρ :

$$\rho = \sum_i p_i \cdot |\phi_i\rangle\langle\phi_i|$$

such that all pure states $|\phi_i\rangle$ are in the diagonal subspace.

2.3 Fidelity

For two (mixed) states ρ and σ in the same quantum system, their *fidelity* is defined as

$$F(\rho, \sigma) = \text{Tr}(\rho^{1/2} \sigma \rho^{1/2}). \quad (3)$$

This definition simplifies if one $\sigma = |\varphi\rangle\langle\varphi|$ is a pure state. Then the fidelity of ρ and σ is

$$F(\rho, |\varphi\rangle\langle\varphi|) = \langle\varphi|\rho|\varphi\rangle \quad (4)$$

In the special case that $|\varphi\rangle = \Psi_N$ is the maximally entangled state, we call the fidelity of ρ and $|\varphi\rangle$ the *fidelity of state* ρ , and the definition simplifies to:

$$F(\rho) = \langle\Psi_N|\rho|\Psi_N\rangle \quad (5)$$

When the state $\rho = |\phi\rangle\langle\phi|$ is also a pure state, we have

$$F(\rho) = F(|\phi\rangle\langle\phi|) = |\langle\phi|\Psi_N\rangle|^2$$

and the fidelity is just the square of the inner product with Ψ_N .

One property for the fidelity is: it is linear with respect to ensembles.

Claim 1 *Let ρ be the density matrix for a mixed state that is an ensemble $\{p_i, |\phi_i\rangle\}$. The fidelity of ρ is the weighted averages of the qualities of the pure states:*

$$F(\rho) = \sum_i p_i \cdot F(|\phi_i\rangle\langle\phi_i|)$$

■

This linearity is particularly convenient in some of the proofs in this paper.

3 General Entanglement Purification Protocols

3.1 The general setting

Alice and Bob are given some entangled state in $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$. They are also given an auxiliary input Ψ_K in $\mathcal{H}_K^A \otimes \mathcal{H}_K^B$. Alice can perform unitary transformations on her part of the state ($\mathcal{H}_N^A \otimes \mathcal{H}_K^A$) and Bob can perform unitary transformations on his part ($\mathcal{H}_N^B \otimes \mathcal{H}_K^B$). Since those transformations only affect one part of the state, they are called *local operations*. Alice and Bob are also allowed to communicate classical bits but not quantum bits. This model is called *LOCC (local operations and classical communication)* [BBP+96a, N99].

If the starting state is unentangled, applying LOCC operations keeps the state unentangled [BBP+96a]. Thus, LOCC operations cannot create entanglement but they can be used to extract the entanglement that already exists in the state.

We use the letter $\mathcal{P}$ to denote protocols for extracting entanglement by LOCC operations. At the end of a protocol $\mathcal{P}$, Alice and Bob have two options:

1. They can abort and claim failure by outputting a special symbol FAIL. We denote this by $\mathcal{P}(\rho) = \text{FAIL}$.
2. They can output a (possibly mixed) state σ in $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$. We denote this by $\mathcal{P}(\rho) = \sigma$.

We now define the error model. We first give an unsuccessful definition to illuminate some of difficulties that we face and to explain the reasons behind our final definition.

3.2 Extracting entanglement from an arbitrary state

Ideally, we would like to have a protocol that takes any entangled state in $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$ with at least a certain amount of entanglement and extracts a state close to Ψ_M for some $M < N$. This would correspond the definition of extractors where extractor can transform any probability distribution with min-entropy at least m into a probability distribution that is close to uniform.

Unfortunately, this is not possible, even if we restrict ourselves to starting states with the maximum possible entanglement. Unlike in the classical world where there is just one probability distribution over N elements with entropy $\log N$ (the uniform distribution), there are infinitely many quantum states with entanglement $\log N$. Namely, any quantum state of the form

$$|\phi\rangle = \sum_{i=0}^{N-1} \alpha_i |i\rangle |i\rangle \quad (6)$$

with $|\alpha_i|^2 = 1/N$ for all $i \in \{0, \dots, N-1\}$ has entanglement $\log N$. In particular, this includes

$$|\phi_j\rangle = \sum_{i=0}^{N-1} \frac{1}{\sqrt{N}} e^{2ij\pi/N} |i\rangle |i\rangle$$

for $j \in \{1, \dots, N\}$. Assume that we have a protocol that extracts Ψ_M from any $|\phi_j\rangle$. This means that, given $|\phi_j\rangle$, the protocol ends with the final state of the form $\Psi_M \otimes |\phi'_j\rangle$. We consider running this protocol on the mixed state ρ that is $|\phi_0\rangle$ with probability $1/N$, $|\phi_2\rangle$ with probability $1/N$, ..., $|\phi_{N-1}\rangle$ with probability $1/N$. Then, the final state is of the form $\Psi_M \otimes \rho'$ where ρ' is some mixed state.

The problem is that ρ is equivalent to the mixed state that is $|0\rangle|0\rangle$ with probability $1/N$, $|1\rangle|1\rangle$ with probability $1/N$, ..., $|N-1\rangle|N-1\rangle$ with probability $1/N$. (This equivalence can be verified by writing out the density matrices of both states.) Neither of states $|i\rangle|i\rangle$ is entangled, so the mixed state obtained by combining them is not entangled as well. Yet, since this mixed state is equivalent to ρ , it gets transformed into $\Psi_M \otimes \rho'$ which is entangled because Ψ_M is entangled.

We have constructed a protocol that transforms an unentangled starting state into entangled end state without quantum communication. Since this is impossible [BBP+96a], our assumption is wrong and there is no protocol that extracts any Ψ_M from an arbitrary $|\phi_j\rangle$.

The argument described above is still valid if we relax the requirement to extracting a state close to Ψ_M and if we allow to use a perfect auxiliary state Ψ_K . In the second case, we can get the perfect Ψ_K back but cannot get an entangled state of higher dimension.

3.3 Extracting from a state close to Ψ_M

The reason for the problem in the previous section is that there are multiple maximally entangled states and combining them into a mixed state can cancel the entanglement and create a state with no entanglement. The consequence is that if we want to be able to extract entanglement we have to restrict ourselves to states that are close to one particular highly entangled state (rather than some highly entangled state). Therefore, we assume that the starting state is close to Ψ_M ².

A common way to measure the closeness to Ψ_M is the fidelity (section 2.3). This gives the following definitions.

²The protocols can be modified to use any other fixed state of the form (6) instead of Ψ_M

Definition 1 (Absolutely Successful GEPP) A General Entanglement Purification Protocol $\mathcal{P}$ is absolutely successful with parameter $\langle N, K, M, \epsilon, \delta \rangle$, if for all states ρ such that $F(\rho) \geq 1 - \epsilon$,

$$\text{Prob} [\mathcal{P}(\rho) = \text{FAIL}] = 0$$

and

$$\text{Prob} [F(\mathcal{P}(\rho)) \geq 1 - \delta] = 1$$

Definition 2 (Deterministically Successful GEPP) A General Entanglement Purification Protocol $\mathcal{P}$ is deterministically conditionally successful with parameter $\langle N, K, M, \epsilon, \delta, p \rangle$, if for all input states ρ such that $F(\rho) = 1 - \epsilon$,

$$\text{Prob} [\mathcal{P}(\rho) = \text{FAIL}] \leq p$$

and

$$\text{Prob} [F(\mathcal{P}(\rho)) \geq 1 - \delta \mid \mathcal{P}(\rho) \neq \text{FAIL}] = 1$$

Definition 3 (Probabilistically Successful GEPP) A General Entanglement Purification Protocol $\mathcal{P}$ is probabilistically conditionally successful with parameter $\langle N, K, M, \epsilon, \delta, p, q \rangle$, if for all input states ρ such that $F(\rho) = 1 - \epsilon$,

$$\text{Prob} [\mathcal{P}(\rho) = \text{FAIL}] \leq p$$

and

$$\text{Prob} [F(\mathcal{P}(\rho)) \geq 1 - \delta \mid \mathcal{P}(\rho) \neq \text{FAIL}] \geq 1 - q$$

Definition 4 (Efficient GEPP) A General Entanglement Purification Protocol $\mathcal{P}$ is efficient, if there exists a constant c such that $\mathcal{P}$ can be implemented by quantum circuits of size $O((\log N + \log K)^c)$.

4 Results

4.1 Impossibility result for absolutely successful protocols

Theorem 1 (a) For all absolutely successful General Entanglement Purification Protocols with parameter $\langle N, K, M, \epsilon, \delta \rangle$, we have the following inequality:

$$\delta \geq \frac{M - K}{M} \frac{N}{N - 1} \epsilon.$$

(b) The bound in (a) is tight. For any integers N, M, K such that NK/M and M/K are both integers, there exists an absolutely successful GEPP with parameter $\langle N, K, M, \epsilon, \frac{M-K}{M} \frac{N}{N-1} \epsilon \rangle$.

This shows that absolutely successful protocols are quite weak. If we just want to extract the auxiliary state Ψ_K and c more EPR pairs, then $M = 2^c K$ and we can achieve the fidelity of at most $1 - \frac{2^c - 1}{2^c} \frac{N}{N - 1} \epsilon < 1 - (1 - \frac{1}{2^c}) \epsilon$ which is less than $\frac{1}{2^c} \epsilon$ better than $1 - \epsilon$ that we had at the beginning. If we want to get Ψ_K plus a linear number of EPR pairs, the improvement in fidelity is an exponentially small fraction of ϵ .

We prove theorem 1 in appendix A.

4.2 Constructions of conditionally successful protocols

On the other hand, there are good conditionally successful protocols.

Theorem 2 *For all integers n, t, d such that $n > t$ and any real $\epsilon < 1/2$, there exist efficient deterministic conditionally successful general entanglement purification protocols of following parameters*

- $\langle 2^n, (2^n - 1), 2^{n-t}(2^n - 1), \epsilon, \frac{\epsilon}{2^t}, \epsilon \rangle$
- $\langle 2^{2n}, 2^n + 1, 2^n(2^n + 1), \epsilon, \frac{\epsilon}{2^n}, \epsilon \rangle$
- $\langle 2^{dn}, \frac{2^{dn}-1}{2^n-1}, 2^{(d-1)n}(\frac{2^{dn}-1}{2^n-1}), \epsilon, \frac{\epsilon}{2^n}, \epsilon \rangle$

for mixed states in the diagonal subspace.

The first protocol achieves the smallest loss of EPR pairs, increasing the fidelity from $1 - \epsilon$ to $1 - \frac{\epsilon}{2^t}$ at the cost of losing just t EPR pairs. It starts with n imperfect EPR pairs and an auxiliary state of dimension $2^n - 1$ and outputs a state of dimension $2^{n-t}(2^n - 1)$. The disadvantage is that we have to use an auxiliary state of almost the same dimension ($2^n - 1$) as the state that we try to purify (2^n). The second and the third construction use smaller auxiliary states but lose more EPR pairs. All 3 results are achieved by Simple Scrambling Protocol (appendix C) using 3 different constructions of scrambling permutations (appendix E).

The constructions fail with probability at most ϵ . We can extend Theorem 2 to show that the trade-off between the probability of failure and increase in fidelity achieved by Theorem 2 is optimal. It might be possible to improve the theorem with respect to other parameters (the dimensionality of the extra state Ψ_K and the amount of entanglement that is lost if the protocol does not fail).

For states not in the diagonal subspace, we can construct a probabilistically successful protocol with almost the same parameters.

Theorem 3 *For all integers n, t, l, d such that $n > t$, $n > l$ and all real $\epsilon < 1/2$, there exist efficient probabilistic conditionally successful general entanglement purification protocols of following parameters*

- $\langle 2^n, (2^n - 1)2^{2t}, 2^{n-t}(2^n - 1), \epsilon, \frac{\epsilon}{2^{t-3}}, 2\epsilon + \sqrt{\frac{2\epsilon}{2^t}}, \frac{1}{2^t} \rangle$
- $\langle 2^{2n}, (2^n + 1)2^{2t}, 2^n(2^n + 1), \epsilon, \frac{\epsilon}{2^{t-3}}, 2\epsilon + \sqrt{\frac{2\epsilon}{2^t}}, \frac{1}{2^t} \rangle$
- $\langle 2^{dn}, \frac{2^{dn}-1}{2^n-1} \cdot 2^{2t}, 2^{(d-1)n}(\frac{2^{dn}-1}{2^n-1}), \epsilon, \frac{\epsilon}{2^{t-3}}, 2\epsilon + \sqrt{\frac{2\epsilon}{2^t}}, \frac{1}{2^t} \rangle$

We note that the extra probability of failure ($\sqrt{\frac{2\epsilon}{2^t}}$) can be made arbitrarily small by increasing t . This theorem is shown by Complete Scrambling protocol which combines the Simple Scrambling protocol with another protocol, Hash-and-Compare (appendix D).

5 Conclusions and Open Problems

We investigated the problem of entanglement purification by Alice and Bob via LOCC. We used a very general model of the input state, where the only information Alice and Bob have is a lower bound on the fidelity of the input state. This contrasts with the previous models which assumed that the “noise” is identical and independent, or Alice and Bob have complete knowledge of the input state they share. Because of the generality of the General Error model, the techniques used in previous works don’t appear viable.

We defined three types of General Entanglement Purification Protocols. Absolutely successful GEPPs never fail, and they always output states that have very high fidelity. Deterministically conditionally successful GEPPs fail with small probability, and otherwise, they output states of high fidelity

with certainty. Probabilistically conditionally successful GEPPs fail with small probability, and otherwise output states of high fidelity with very high probability.

We proved a negative result that there don't exist absolutely successful GEPPs of interesting parameters, i.e., on average, the ability of Alice and Bob to purify the entanglement is very limited.

We constructed efficient GEPPs that are deterministically conditionally successful for mixed states in the diagonal subspace (Simple Scrambling protocol) and probabilistically conditionally successful for an arbitrary state of sufficiently high fidelity (Complete Scrambling protocol).

In our construction of the protocols, Scrambling Permutations play a very important role. We give 3 different constructions of efficient Scrambling Permutations in Appendix E. Each construction has its own advantage. By plugging them into the construction of Complete Scrambling protocol, we obtain different protocols with different parameters. We notice that the notion of Scrambling Permutations are closely related to universal hash functions. By being more lax on the “scrambling” property, they can have more efficient constructions than universal hash functions.

There are several open problems:

1. **Remove the auxiliary input or reduce its size.** In our paper, both the Simple Scrambling protocol and the Hash and Compare protocol need maximally entangled states as auxiliary input. The Simple Scrambling protocol needs them to “scramble” the coefficients of the input state, and the Hash and Compare protocol needs them to perform teleportation. In the final construction of the Complete Scrambling protocols, if Alice and Bob share an input of n_0 qubit pairs, they need to invest $O(n_0)$ perfect EPR pairs in order to perform the purification. It would be very desirable to reduce the number of auxiliary perfect EPR pairs as much as possible: the ideal case would be removing them completely, but even reducing them to $o(n_0)$ would be interesting.
2. **Optimal GEPPs** The Simple Scrambling protocol is optimal in the sense that the average fidelity of its output matches the upper bound of Theorem 1 asymptotically (in case Alice and Bob fail, they can output $|Z_M\rangle^A \otimes |Z_M\rangle^B$ instead). However it is not true for Hash and Compare and Complete Scrambling protocols. Do there exist optimal GEPPs that work for all states?
3. **Relationship to classical randomness extraction.** As we described in the introduction, we view the problem of extracting entanglement as a quantum counterpart of extracting randomness from a weak random source. There is also a similarity between the techniques used in those two problems. One of the main techniques used in the classical randomness extraction is the universal hash function, and we used scrambling permutations in our construction of GEPP. Are there deeper relationships between the two problems? Also, can some of the techniques from classical randomness extractors be used in the entanglement purification? Notice that the state of art in randomness extraction is that only logarithmic number of truly random bits need to be invested and almost all the entropy can be extracted [NT99], whereas in the case of entanglement extraction, our constructions call for linear number of perfect EPR pairs to be invested and considerable amount of entanglement is wasted. Can we make the entanglement purification protocols more efficient, or are these inefficiencies inherent?

Acknowledgment

The authors would like to thank Bob Griffith and Steven Rudich for enlightening discussions. The authors thank John Langford for proof-reading the earlier version of this paper.

A Tight bounds on Absolutely Successful GEPPs

We prove Theorem 1 in this section.

A.1 A Negative Result

We show that on average, Alice and Bob cannot increase the fidelity of their input state significantly, even if they have an auxiliary input Ψ_K .

We first study a simpler problem. Suppose Alice and Bob share a maximally entangled state Ψ_K and some private ancillary bits, initialized to $|0\rangle$. We describe this shared state by

$$|\phi\rangle = (|Z_N\rangle^A \otimes |Z_N\rangle^B) \otimes \Psi_K$$

The fidelity of this state is K/M by a simple computation.

Alice and Bob try to convert state $|\phi\rangle$ as close to Ψ_M as possible by LOCC. The problem is: how close can they get? If M/K is an integer, Alice and Bob just trace out a subsystem of their ancillary bits to bring the dimension of each their subsystem to M , then they obtain a state

$$|\psi_0\rangle = (|Z_{M/K}\rangle^A \otimes |Z_{M/K}\rangle^B) \otimes \Psi_K$$

which has fidelity K/M by a straightforward computation. In fact, this is actually the best Alice and Bob can do:

Lemma 1 *Let $|\phi\rangle = (|Z_N\rangle^A \otimes |Z_N\rangle^B) \otimes \Psi_K$ be a state in a bipartite system $\mathcal{H}_{NK}^A \otimes \mathcal{H}_{NK}^B$ shared between Alice and Bob. Let σ be the state Alice and Bob output after performing LOCC operations. Suppose that σ is in the subspace $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$. We have $F(\sigma) \leq \frac{K}{M}$. ■*

This lemma is a direct corollary of a result by Vidal, Jonathan, and Nielsen [VJN00]. There is also a simple direct proof in Appendix B.

Proof: [Proof to Theorem 1, part (a)]

We prove the theorem by demonstrating a particular mixed state ρ such that ρ has a fidelity $1 - \epsilon$, and no LOCC can increase its fidelity to more than $1 - \frac{M-K}{M} \frac{N}{N-1} \epsilon$.

Let $\epsilon' = \frac{N}{N-1} \epsilon$. We define the state ρ to be

$$\rho = (1 - \epsilon') \cdot |\Psi_N\rangle\langle\Psi_N| + \epsilon' \cdot |Z_N^A \otimes Z_N^B\rangle\langle Z_N^A \otimes Z_N^B|$$

In fact, ρ is the maximally entangled state Ψ_M with probability $(1 - \epsilon')$ and the totally disentangled state $Z_N^A \otimes Z_N^B$ with probability ϵ' .

It is easy to verify that $F(\rho) = 1 - \epsilon$, since $\langle\Psi_N|Z_N^A \otimes Z_N^B\rangle = 1/\sqrt{N}$ and, therefore,

$$F(\rho) = (1 - \epsilon')F(|\Psi_N\rangle\langle\Psi_N|) + \epsilon'F(|Z_N^A \otimes Z_N^B\rangle\langle Z_N^A \otimes Z_N^B|) = (1 - \epsilon') + \frac{1}{N}\epsilon' = 1 - (1 - \frac{1}{N})\epsilon' = 1 - \epsilon.$$

For an arbitrary GEPP $\mathcal{P}$ that never fails, we define

$$f_1 = F(\mathcal{P}(|\Psi_N\rangle\langle\Psi_N|))$$

and

$$f_2 = F(\mathcal{P}(|Z_N^A \otimes Z_N^B\rangle\langle Z_N^A \otimes Z_N^B|))$$

Then we have $f_1 \leq 1$ and by Lemma 1, $f_2 \leq K/M$.

By the linearity of fidelity of quantum operations, we know that

$$F(\mathcal{P}(\rho)) = (1 - \epsilon')f_1 + \epsilon'f_2 \leq 1 - \frac{M-K}{M}\epsilon' = 1 - \frac{M-K}{M} \frac{N}{N-1} \epsilon.$$

We will prove the part (b) of the theorem in the next subsection. ■

Therefore, there don't exist absolutely successful GEPPs with very interesting parameters — we hope that our protocol is able to “boost” the fidelity of the input state to arbitrarily close to 1, but clearly this is impossible for absolutely successful protocols.

A.2 A Protocol That Matches the Bound

We now prove the second part Theorem 1, that the bound is tight. We do so by showing that there is a protocol that achieves this slight increase in fidelity.

The input to the protocol is a state ρ in $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$. The protocol outputs a state in $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$ where $M < N$ and M divides N . There is no auxiliary state used, i.e., $K = 1$.

Construction 1 (Random Permutation Protocol) *The input to this protocol is a state in $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$. The steps are:*

1. Alice generates a uniformly random permutation π on N elements using classical randomness and transmits the permutation to Bob.
2. Alice applies permutation π on $\mathcal{H}_N^A$, mapping $|i\rangle$ to $|\pi(i)\rangle$, Bob does the same on $\mathcal{H}_N^B$.
3. Alice and Bob decompose $\mathcal{H}_N$ as $\mathcal{H}_M \otimes \mathcal{H}_L$, $L = N/M$ and measure the $\mathcal{H}_L$ part.
4. Alice sends the result of her measurement to Bob, Bob sends his result to Alice.
5. They compare the results. If the results are the same, they output the state that they have in $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$. If the results are different, they output $|Z_M\rangle \otimes |Z_M\rangle$.

We start with the case when the state of Alice and Bob is in the diagonal subspace.

Lemma 2 *If the input state to the Random Permutation Protocol is in the diagonal subspace, the protocol is absolutely successful with parameters $\langle N, 1, M, \epsilon, \frac{M-1}{M} \frac{N}{N-1} \epsilon \rangle$.*

Proof: Without loss of generality, we assume that the starting state is pure. Let $|\phi\rangle = \sum_{i=1}^N \alpha_i |i\rangle^A |i\rangle^B$ be the starting state. For a permutation π , let U_π be the unitary transformation defined by $U_\pi(|i\rangle^A \otimes |j\rangle^B) = |\pi(i)\rangle^A |\pi(j)\rangle^B$. Then, if Alice and Bob use a permutation π , the resulting state is

$$|\phi_\pi\rangle = U_\pi |\phi\rangle = \sum_{i=1}^N \alpha_i |\pi(i)\rangle^A |\pi(i)\rangle^B = \sum_{i=1}^N \alpha_{\pi^{-1}(i)} |i\rangle^A |i\rangle^B.$$

There are $N!$ permutations π on a set of N elements. Therefore, each of them gets applied with probability $1/N!$. This means that the final state is a mixed state of $|\phi_\pi\rangle$ with probabilities $1/N!$ each. We calculate the density matrix ρ of this state. It is equal to

$$\sum_{\pi} \frac{1}{N!} |\phi_\pi\rangle \langle \phi_\pi| = \sum_{\pi} \frac{1}{N!} \begin{pmatrix} \alpha_{\pi^{-1}(1)} \alpha_{\pi^{-1}(1)}^* & \alpha_{\pi^{-1}(1)} \alpha_{\pi^{-1}(2)}^* & \dots & \alpha_{\pi^{-1}(1)} \alpha_{\pi^{-1}(N)}^* \\ \alpha_{\pi^{-1}(2)} \alpha_{\pi^{-1}(1)}^* & \alpha_{\pi^{-1}(2)} \alpha_{\pi^{-1}(2)}^* & \dots & \alpha_{\pi^{-1}(2)} \alpha_{\pi^{-1}(N)}^* \\ \dots & \dots & \dots & \dots \\ \alpha_{\pi^{-1}(N)} \alpha_{\pi^{-1}(1)}^* & \alpha_{\pi^{-1}(N)} \alpha_{\pi^{-1}(2)}^* & \dots & \alpha_{\pi^{-1}(N)} \alpha_{\pi^{-1}(N)}^* \end{pmatrix}.$$

We claim that all diagonal entries ρ_{ii} are equal to $1/N$ and all off-diagonal entries ρ_{ij} , $i \neq j$ are equal to some value a which is real. This follows from the symmetries created by summing over all permutations.

Consider a diagonal entry ρ_{ii} . For each $j \in \{1, \dots, N\}$, there are $(N-1)!$ permutations that map j to i . Therefore,

$$\rho_{ii} = \sum_{j=1}^N (N-1)! \frac{1}{N!} \alpha_j \alpha_j^* = \frac{1}{N} \sum_{j=1}^N |\alpha_j|^2.$$

$\sum_{j=1}^N |\alpha_j|^2$ is the same as $\|\phi\|^2$ which is equal to 1. Therefore, $\rho_{ii} = \frac{1}{N}$.

Next, consider an off-diagonal entry ρ_{ij} . For each k, l , $k \neq l$, there are $(N-2)!$ permutations that map k to i and l to j . Therefore,

$$\rho_{ij} = \sum_{k=1}^N \sum_{l=1, l \neq k}^N (N-2)! \frac{1}{N!} \alpha_k \alpha_l^* = \sum_{k=1}^N \sum_{l=1, l \neq k}^N \frac{1}{N(N-1)} \alpha_k \alpha_l^*.$$

This immediately implies that ρ_{ij} is the same for all $i \neq j$. Also, notice that $(\alpha_k \alpha_l^*)^* = \alpha_k^* \alpha_l$. Therefore, $\alpha_k \alpha_l^* + \alpha_l \alpha_k^*$ is real and ρ_{ij} (which is a sum of terms of this form) is real as well. Let $a = \rho_{ij}$. We have shown that

$$\rho = \begin{pmatrix} \frac{1}{N} & a & \dots & a \\ a & \frac{1}{N} & \dots & a \\ \dots & \dots & \dots & \dots \\ a & a & \dots & \frac{1}{N} \end{pmatrix}.$$

Notice that the density matrix ρ can be also obtained from a mixed state that is Ψ_N with probability Na and each of basis states $|i\rangle^A |i\rangle^B$ with probability $\frac{1}{N} - a$.

We now consider applying steps 3-5 to those states. Measuring $\mathcal{H}_L^A \otimes \mathcal{H}_L^B$ for $|\Psi_N\rangle$ always gives the same results and leaves Alice and Bob with the state $|\Psi_M\rangle$ in $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$. The fidelity of this state with $|\Psi_M\rangle$ is, of course, 1. Measuring $\mathcal{H}_L^A$ and $\mathcal{H}_L^B$ for $|i\rangle^A |i\rangle^B$ also gives the same results and leaves Alice and Bob with some basis state $|i'\rangle^A |i'\rangle^B$ in the diagonal subspace of $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$. The fidelity of this state and $|\Psi_M\rangle$ is $\frac{1}{M}$. By Claim 1, if we apply those steps to the state ρ , we get that the final fidelity

$$Na + N \left(\frac{1}{N} - a \right) \frac{1}{M} = \frac{1}{M} + Na \left(1 - \frac{1}{M} \right). \quad (7)$$

We now lower-bound a . By Claim 1, $F(\rho) = \frac{1}{N!} \sum_{\pi} F(|\phi_{\pi}\rangle)$. Since permuting the basis states $|i\rangle^A |i\rangle^B$ preserves the maximally entangled state $\Psi_N = \frac{1}{\sqrt{N}} \sum_{i=1}^N |i\rangle^A |i\rangle^B$, the fidelity of any $|\phi_{\pi}\rangle$ is the same as the fidelity of $|\phi\rangle$. Therefore, $F(\rho) = F(|\phi\rangle) \geq 1 - \epsilon$. By applying the definition of fidelity,

$$F(\rho) = \left(\begin{matrix} \frac{1}{\sqrt{N}} \\ \frac{1}{\sqrt{N}} \\ \dots \\ \frac{1}{\sqrt{N}} \end{matrix} \right) \left(\begin{matrix} \frac{1}{N} & a & \dots & a \\ a & \frac{1}{N} & \dots & a \\ \dots & \dots & \dots & \dots \\ a & a & \dots & \frac{1}{N} \end{matrix} \right) \left(\begin{matrix} \frac{1}{\sqrt{N}} & \frac{1}{\sqrt{N}} & \dots & \frac{1}{\sqrt{N}} \end{matrix} \right) = N \frac{1}{N^2} + N(N-1) \frac{1}{N} a = \frac{1}{N} + (N-1)a.$$

Since $F(\rho) \geq 1 - \epsilon$, it must be the case that $a \geq \frac{1}{N} - \frac{\epsilon}{N-1}$. By substituting that into (7), the fidelity of the final state with $|\Psi_M\rangle$ is at least

$$\frac{1}{M} + N \left(\frac{1}{N} - \frac{\epsilon}{N-1} \right) \left(1 - \frac{1}{M} \right) = 1 - \frac{N}{N-1} \left(1 - \frac{1}{M} \right) \epsilon.$$

■

To prove the second part of Theorem 1, it remains to show that the protocol also succeeds for states not in the diagonal subspace. Let $|\phi\rangle$ be a state such that $F(|\phi\rangle) \geq 1 - \epsilon$. We decompose

$$|\phi\rangle = \sqrt{1-\delta} |\phi_1\rangle + \sqrt{\delta} |\phi_2\rangle,$$

with $|\phi_1\rangle \in \mathcal{H}^D$ and $|\phi_2\rangle \in (\mathcal{H}^D)^\perp$. Let $F(|\phi_1\rangle) = 1 - \delta'$. Since Ψ_N is in $\mathcal{H}^D$ and $|\phi_2\rangle$ is orthogonal to $\mathcal{H}^D$, we have $F(|\phi_2\rangle) = 0$ and $F(|\phi\rangle) = (1-\delta)(1-\delta')$. Notice that $(1-\delta)(1-\delta') \geq 1 - \epsilon$ because $F(|\psi\rangle) \geq 1 - \epsilon$.

Applying U_π maps $|\phi\rangle$ to $|\phi_\pi\rangle = \sqrt{1-\delta} |\phi_{\pi,1}\rangle + \sqrt{\delta} |\phi_{\pi,2}\rangle$ where $|\phi_{\pi,1}\rangle = U_\pi |\phi_1\rangle$, $|\phi_{\pi,2}\rangle = U_\pi |\phi_2\rangle$. Since U_π preserves the diagonal subspace, $|\phi_{\pi,1}\rangle \in \mathcal{H}^D$ and $|\phi_{\pi,2}\rangle \in (\mathcal{H}^D)^\perp$. Measuring $\mathcal{H}_L^A$ and $\mathcal{H}_L^B$ for

a state in $\mathcal{H}^{\mathcal{D}}$ always gives the same results and produces a state in the diagonal subspace of $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$. Measuring $\mathcal{H}_L^A$ and $\mathcal{H}_L^B$ for a state in $(\mathcal{H}^{\mathcal{D}})^{\perp}$ either gives the different results for Alice and Bob or gives the same results but produces a state orthogonal to the diagonal subspace of $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$.

The fidelity of the final state consists of two parts: the fidelity of the final state if Alice's and Bob's measurements of $\mathcal{H}_L$ give the same answer and the fidelity if measurements give the different answer. The first part is just $(1 - \delta)$ times the fidelity of the final state if the starting state was $|\phi_1\rangle$ (instead of $|\phi\rangle$). Since $|\phi_1\rangle$ is in the diagonal subspace, Lemma 2 implies that the final state of the protocol $|\phi_1\rangle$ has the fidelity at least $1 - D\delta'$ where $D = \frac{M-1}{M} \frac{N}{N-1}$. Therefore, the first part is at least

$$(1 - \delta)(1 - D\delta') = (1 - \delta)(1 - \delta') + (1 - D)\delta'(1 - \delta) \quad (8)$$

The second part is the probability of measurements giving different answers times the fidelity of the state $|0\rangle \otimes |0\rangle$ which Alice and Bob output in this case. The fidelity of this state is $\frac{1}{M}$ and the probability of this case is given by

Lemma 3 *The probability that Alice's and Bob's measurements give different answers is $\frac{N-M}{N-1}\delta$.*

Proof: First, we look at the state $|\phi_2\rangle$. Since this state is in $(\mathcal{H}^{\mathcal{D}})^{\perp}$, it is of the form

$$|\phi_2\rangle = \sum_{i,j=1, i \neq j}^N \alpha_{i,j} |i\rangle^A |j\rangle^B.$$

Applying U_{π} maps it to

$$|\phi_{\pi,2}\rangle = \sum_{i \neq j} \alpha_{i,j} |\pi(i)\rangle^A |\pi(j)\rangle^B = \sum_{i \neq j} \alpha_{\pi^{-1}(i), \pi^{-1}(j)} |i\rangle^A |j\rangle^B.$$

The probability of Alice and Bob getting different results is equal to the sum of $|\alpha_{\pi^{-1}(i), \pi^{-1}(j)}|^2$ over all basis $|i\rangle^A, |j\rangle^B$ that differ in the $\mathcal{H}_L$ part. If this sum is averaged over all permutations π , it becomes the same for all $i, j, i \neq j$. Therefore, the probability of Alice and Bob getting different results is just the fraction of pairs (i, j) that differ in the $\mathcal{H}_L$ part. It is $\frac{N-M}{N-1}$ because for each i , there are $(N-1)$ $j \in \{1, \dots, N\}, j \neq i$ and $M-1$ of them differ only in the $\mathcal{H}_K$ but the remaining $N-M$ differ in the $\mathcal{H}_L$ part.

If the starting state is $|\phi\rangle$, the probability of Alice and Bob getting different results is δ times the probability for $|\phi_2\rangle$ because $|\phi\rangle = \sqrt{1-\delta}|\phi_1\rangle + \sqrt{\delta}|\phi_2\rangle$ and the measurements always give the same answer on $|\phi_1\rangle$. ■

Therefore, the second part of the fidelity is $\frac{1}{M} \frac{N-M}{N-1} \delta$. Notice that $1 - D = 1 - \frac{(M-1)N}{M(N-1)} = \frac{(M-1)N - M(N-1)}{M(N-1)} = \frac{N-M}{M(N-1)}$. Thus, the second part is $(1 - D)\delta$ and the overall fidelity is at least

$$(1 - \delta)(1 - \delta') + (1 - D)(1 - \delta)\delta' + (1 - D)\delta = 1 - D(\delta(1 - \delta') + \delta').$$

Since $(1 - \delta)(1 - \delta') \geq 1 - \epsilon$, $\delta(1 - \delta') + \delta' \leq \epsilon$. Therefore, the overall fidelity is at least $1 - D\epsilon$. This completes the proof of the second part of Theorem 1 for $K = 1$.

For $K > 1$, we can just produce an entangled state of dimension $M' = M/K$ without the use of $|\Psi_K\rangle$ by the protocol above and then output this state and the original $|\Psi_K\rangle$. This achieves the fidelity of at least $1 - D\epsilon$ for $D = \frac{M'-1}{M'} \frac{N}{N-1} = \frac{M/K-1}{M/K} \frac{N}{N-1} = \frac{M-K}{M} \frac{N}{N-1}$, proving that the bound of Theorem 1 (a) is tight for $K > 1$ as well.

B Proof to Lemma 1

We give a (somewhat) simpler proof to Lemma 1 than the proof by Vidal, Jonathan, and Nielsen [VJN00].

For a self-adjoint matrix M , we define its *spectrum* written as $\mathcal{S}(M)$, to be a vector formed by the eigenvalues of M , and whose entries are sorted in a decreasing order. In other words, if the eigenvalues of M are $\lambda_1, \lambda_2, \dots, \lambda_d$, where $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_d$, then $\mathcal{S}(M) = (\lambda_1, \lambda_2, \dots, \lambda_d)$.

For a mixed state ρ , if we write ρ as

$$\rho = \sum_{i=1}^d p_i \cdot |\phi_i\rangle\langle\phi_i|$$

where $p_1 \geq p_2 \geq \dots \geq p_d$, and $\{|\phi_i\rangle\}$ is an orthonormal basis, then

$$\mathcal{S}(\rho) = (p_1, p_2, \dots, p_d)$$

A useful Fact about the spectrum of a tensor product of two matrices is the following:

Fact 1 *Let A and B be square matrices such that the eigenvalues for A are $\{\lambda_1, \lambda_2, \dots, \lambda_m\}$ and the eigenvalues for B are $\{\mu_1, \mu_2, \dots, \mu_n\}$. Then the eigenvalues for the matrix $A \otimes B$ are $\{\lambda_i \cdot \mu_j\}_{i=1,2,\dots,m, j=1,2,\dots,n}$.*

Proof: It is easy to verify that if $A \cdot \vec{v} = \lambda \cdot \vec{v}$ and $B \cdot \vec{u} = \mu \cdot \vec{u}$, then $(A \otimes B) \cdot (v \otimes u) = (\lambda \cdot \mu)(v \otimes u)$ ■

and a corollary the above fact is:

Corollary 1 *Let ρ^A, ρ^B be the density matrices for quantum systems $\mathcal{H}^A$ and $\mathcal{H}^B$. Then we have*

$$\text{rank}(\rho^A \otimes \rho^B) \geq \text{rank}(\rho^A) \quad (9)$$

Proof: Notice that the rank of a matrix equals the number of non-zero eigenvalues of this matrix. Since ρ^B is a density matrix, it has trace 1, and thus it has at least one non-zero eigenvalue — assume it is μ_1 . We denote the eigenvalues of ρ^A by $\lambda_1, \lambda_2, \dots, \lambda_m$, then by Fact 1, $\lambda_1 \cdot \mu_1, \lambda_2 \cdot \mu_1, \dots, \lambda_m \cdot \mu_1$ are all eigenvalues of $\rho^A \cdot \rho^B$, and they contain at many non-zero numbers as the eigenvalues of ρ^A . ■

Proof: [Proof to Lemma 1]

We consider an arbitrary protocol $\mathcal{P}$ between Alice and Bob involving only LOCC. We assume that $\mathcal{P}$ consists of *steps*, where each step could be one of the following operations ³:

1. **Unitary Operation:**

Alice (or Bob) applies a unitary operation to her (or his) subsystem.

2. **Measurement:**

Alice (or Bob) performs a measurement to her (or his) subsystem.

3. **Tracing Out:**

Alice (or Bob) discards part of her (or his) subsystem, or equivalently, traces out part of the subsystem.

4. **Classical Operation:**

Alice (or Bob) sends a (classical) message to the other party.

³We assume that Alice have enough ancillary qubit at the beginning of the protocol and not more new ancillary qubits need to be introduced during the protocol.

We first convert this protocol $\mathcal{P}$ into another protocol $\mathcal{P}'$ in the following way: for each tracing-out operation Alice (or Bob) performs, we insert a measurement operation right before the tracing-out, and the measurement is a full measurement of the subsystem to be traced out. Notice that $\mathcal{P}'$ will have exactly the same output as $\mathcal{P}$, since the subsystem that was traced out isn't part of the output. However, $\mathcal{P}'$ has the property that for each subsystem traced out in the protocol, that subsystem is disentangled from the rest, since it is already completely measured.

Now we analyze the new protocol $\mathcal{P}'$. We denote the partial density matrix of Alice for the state $|\phi\rangle$ by ρ^A :

$$\rho^A = \text{Tr}_B(|\phi\rangle\langle\phi|) \quad (10)$$

Since we know $|\phi\rangle$ precisely, we can compute ρ^A precisely, and in particular, its spectrum. It is easy to verify that the spectrum of ρ^A is

$$\mathcal{S}(\rho^A) = (\underbrace{1/K, 1/K, \dots, 1/K}_K, \underbrace{0, 0, \dots, 0}_{(N-1)K})$$

So the rank of ρ^A (which is also the Schmidt Number of $|\phi\rangle$) is K .

We focus on how ρ^A changes with the local operations Alice performs (apparently it doesn't change with Bob's local operations): we shall prove that the rank of ρ^A never increases. There are 3 types of operations Alice can perform: unitary operations, local measurements, and tracing out a subsystem, we analyze them one by one:

- **Unitary Operations**

This operation changes a mixed state ρ^A to $U\rho^A U^\dagger$, where U is a unitary operation. Obviously the rank doesn't change.

- **Local Measurements**

Suppose measurement operator is $\{M_m\}$ satisfying $\sum_m M_m^\dagger M_m = I$, and the measurement yields result m . Then Alice ends in state

$$\rho_m = \frac{M_m \rho^A M_m^\dagger}{\text{Tr}(M_m^\dagger M_m \rho^A)}$$

Again, we have $\text{rank}(\rho_m) \leq \text{rank}(\rho^A)$.

- **Tracing Out a Subsystem**

We write $\mathcal{H}^A = \mathcal{H}^{A_0} \otimes \mathcal{H}^{A_1}$, and we suppose that the subsystem $\mathcal{H}^{A_1}$ is traced out. We write the partial density matrix for $\mathcal{H}^{A_0}$ as ρ^{A_0} , and we have $\rho^{A_0} = \text{Tr}_{A_1}(\rho^A)$.

We know that in protocol $\mathcal{P}'$, the subsystem $\mathcal{H}^{A_0}$ is disentangled from the subsystem $\mathcal{H}^{A_1}$. Thus we have

$$\rho^A = \rho^{A_0} \otimes \rho^{A_1}$$

for some density matrix ρ^{A_1} . and by Corollary 1, we have $\text{rank}(\rho^{A_0}) \leq \text{rank}(\rho^A)$.

So, as Alice and Bob perform local operations, the rank of the partial density matrix for Alice never increases. This fact remains true even if Alice and Bob perform classical communications (this just means that Alice has the ability to perform different local operations according to Bob's measurement result, but no local operation Alice performs can increase the rank).

We denote the density matrix for the final state after the protocol $\mathcal{P}$ to be ρ_E , and we define $\rho_E^A = \text{Tr}_B(\rho_E)$ to be the partial density matrix for Alice. Then we have $\text{rank}(\rho_E^A) \leq K$. Notice ρ_E^A should be an $M \times M$ matrix since Alice and Bob are supposed to arrive at a state in $\mathcal{H}_M^A \otimes \mathcal{H}_M^B$. We use ρ_0^A to denote the partial density matrix for Alice if we trace out the system $\mathcal{H}_M^B$ from the target state Ψ_M . It is easy to verify that $\rho_0^A = \frac{1}{M}I$, where I is the identity matrix.

By monotonicity of fidelity, we have

$$F(\rho_E, |\Psi_M\rangle\langle\Psi_M|) \leq F(\rho_E^A, \rho_0^A)$$

However, we have

$$\begin{aligned} F(\rho_E^A, \rho_0^A) &= \text{Tr} \sqrt{(\rho_E^A)^{1/2} \rho_0^A (\rho_E^A)^{1/2}} \\ &= \sqrt{\frac{1}{M}} \cdot \text{Tr} \sqrt{\rho_E^A} \end{aligned}$$

We write the spectrum of ρ_E^A as

$$\mathcal{S}(\rho_E^A) = (\lambda_1, \lambda_2, \dots, \lambda_M)$$

and we know that $\lambda_{K+1} = \lambda_{K+2} = \dots = \lambda_M = 0$ since $\text{rank}(\rho_E^A) \leq K$. Therefore, we have

$$\text{Tr} \sqrt{\rho_E^A} = \sum_{l=1}^M \sqrt{\lambda_l} = \sum_{l=1}^K \sqrt{\lambda_l} \leq \sqrt{K} \cdot \left(\sum_{l=1}^K \lambda_l \right) = \sqrt{K}$$

and thus

$$F(\rho_E^A, \rho_0^A) = \sqrt{\frac{1}{M}} \cdot \text{Tr} \sqrt{\rho_E^A} \leq \sqrt{\frac{K}{M}}$$

Therefore we have

$$F(\rho_E) = F(\rho_E, |\Psi_M\rangle\langle\Psi_M|) \leq F(\rho_E^A, \rho_0^A) \leq \frac{K}{M}$$

■

C Constructions of Deterministically Conditionally Successful GEPPs

We describe the construction of the “Simple Scrambling” protocol. This protocol is deterministically conditionally successful GEPP for input states in the diagonal subspace.

The construction relies on a special family of permutations, namely the Scrambling Permutations. We give a definition of Scrambling Permutations first, and postpone the actual construction of these permutations to the Appendix E.

C.1 Scrambling Permutations

We define a class of permutations that would be useful in constructing the Simple Scrambling protocol. We work on functions over binary strings, and we use $x \circ y$ to denote string x concatenated with string y . For finite sets A and B of binary strings, we define the *concatenation* of A and B to be set

$$A \circ B = \{a \circ b \mid a \in A, b \in B\}$$

We will be working with 4 finite sets of binary strings, and we call them X , Y , G , and H . These sets have the property that $X = G \circ H$. We define $N = |X|$, $K = |Y|$, $W = |H|$, $L = |G|$, and we will be using this size convention for the rest of this paper. Obviously we have $N = WL$.

Definition 5 (Scrambling Permutation) *A class of parameterized function pairs $\langle g_y(x), h_y(x) \rangle$ of types $g_y : X \mapsto G$ and $h_y : X \mapsto H$ is called a scrambling permutation pair of parameter (N, K, W, L) , or simply scrambling permutation, if the following 2 conditions are satisfied:*

1. **(Permutation)** *For all $y \in Y$, $x \mapsto g_y(x) \circ h_y(x)$ is a permutation in X .*

2. **(Scrambling)** *There exists a positive number p , such that for any pair of elements $x_1 \neq x_2$ in X ,*

$$\text{Prob}_y[h_y(x_1) = h_y(x_2)] = p$$

where the probability is taken over the y uniformly chosen from Y . We call this p the “collision probability”.

Furthermore, the pair will be called efficient scrambling permutation pair if both the function $g_y(x) \circ h_y(x)$ and its inverse can be efficiently computed (i.e., has polynomial-size circuits).

It is interesting to compare the definition of scrambling permutations to that of universal hash functions [CW79, WC81]. On one hand, the scrambling permutations are permutations, while the universal hash functions don’t have to be. On the other hand, the “scrambling” property in the scrambling permutation is weaker than that of the universal hash functions. For scrambling permutations, the function $h_y(x)$ only need to have a constant collision probability for all pairs (x_1, x_2) . However, for universal hash functions, the setting is that $\text{Prob}_y[h_y(x_1) = a \wedge h_y(x_2) = b]$ is the same for all (x_1, x_2, a, b) tuples. Obviously, any universal hash function that can be extended to a permutation will induce a scrambling permutation. An example is the linear map construction ($f_{a,b}(x) = a \cdot x + b$, see [MR95], page 219, or [L96], page 85). However, there exist more efficient constructions of scrambling permutations — We postpone the detailed construction and discussion to Appendix E, and we just state the results here:

Theorem 4 *There exist efficient scrambling permutations with the following parameters:*

- $\langle 2^n, (2^n - 1), 2^{n-t}, 2^t \rangle$
- $\langle 2^{2n}, (2^n + 1)2^{2t}, 2^n, 2^n \rangle$
- $\langle 2^{dn}, \frac{2^{dn}-1}{2^n-1} \cdot 2^{2t}, 2^{(d-1)n}, 2^n \rangle$

where n, t, d are integers such that $n > t$. ■

A useful fact about Scrambling Permutation is that the collision probability p can be computed.

Theorem 5 *Let $\langle g_y(x), h_y(x) \rangle$ be a scrambling permutation pairs of parameter $\langle N, K, W, L \rangle$. The collision probability p equals $(L - 1)/(N - 1)$.*

Proof: We call a triple $\langle x_1, x_2, y \rangle$ a “collision instance”, if $h_y(x_1) = h_y(x_2)$. Now we count how many such collision instances there are. There are two ways to count them.

- For each (x_1, x_2) pair, there are $K \cdot p$ y ’s such that $h_y(x_1) = h_y(x_2)$. So the total number of collision instances is

$$Kp \cdot N(N - 1)/2$$

- For each fixed $h_y(\cdot)$, it is a function that maps X of size N to H of size W . Since $g_y \cdot h_y$ is a permutation, the mapping $h_y(x)$ has to be an “even” one: for each $u \in H$, there must be precisely L elements in X that are mapped to u . So the N elements in X are partitioned into W subsets, each of size L . The number of pairs that are in the same subset is therefore $W \cdot L(L - 1)/2$. So the number of collision instances is

$$K \cdot W \cdot L(L - 1)/2$$

The two ways should give the same result. Thus we have

$$Kp \cdot N(N - 1)/2 = K \cdot W \cdot L(L - 1)/2$$

or

$$p = \frac{L - 1}{N - 1}$$
■

C.2 The Construction of the Simple Scrambling Protocol

We describe the construction of the Simple Scrambling protocol, which is deterministically conditional successful for input states in the diagonal subspace.

First, we recall the definitions of the Fourier Operator and the Hadamard Operator.

For a Hilbert space of dimension N , the *Fourier Operator* is defined by the matrix F where the (x, y) -th entry of F is $\frac{1}{\sqrt{N}}\omega^{-x \cdot y}$, for $x, y = 0, 1, \dots, N-1$, where $\omega = e^{i\frac{2\pi}{N}}$ is a root of the unity, and $x \cdot y$ denotes the integer multiplication. F is a unitary operator. We call its inverse, $F^\dagger$, the *Inverse Fourier Operator*.

For a Hilbert space of dimension $N = 2^n$, the *Hadamard Operator* is defined by the matrix H where the (x, y) -th entry of H is $\frac{1}{\sqrt{N}}(-1)^{x \bullet y}$, where $x \bullet y$ is the inner product of x and y , for $x, y = 0, 1, \dots, N-1$.

This protocol is parameterized by 4 integers: N, K, W, L , such that there exists a scrambling permutation pair $\langle g_y(x), h_y(x) \rangle$ of parameter (N, K, W, L) .

Construction 2 (Simple Scrambling Protocol) *The input to the protocol is a state ρ in $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$. The protocol also has an auxiliary input of Ψ_K . The steps are:*

1. *Alice and Bob both apply the scrambling permutation to their qubits: using the qubits from ρ as x and the qubits from Ψ_K as y , and outputs the values of both functions and y :*

$$|x\rangle|y\rangle \longrightarrow |g_y(x)\rangle|h_y(x)\rangle|y\rangle \quad (11)$$

Here we identify the Hilbert space $\mathcal{H}_N \otimes \mathcal{H}_K$ with $\mathcal{H}_L \otimes \mathcal{H}_W \otimes \mathcal{H}_K$.

2. *Alice applies the Fourier Operator to the state $|g_y(x)\rangle^A$, and Bob applies the Inverse Fourier Operator to the state $|g_y(x)\rangle^B$. Then both measure these qubits in the computational basis.*
In the case that L is a power of 2, Alice and Bob can, alternatively, both apply a Hadamard operator to their states of $|g_y(x)\rangle$, instead of the Fourier and Inverse Fourier operators.
3. *Alice and Bob compare their results via classical communication.*
4. *If the results are the same, they discard the measured state (or equivalently, trace out the subspace $\mathcal{H}_L$), and output the remaining state, which is in Hilbert space $\mathcal{H}_{WK}^A \otimes \mathcal{H}_{WK}^B$.*
5. *If the results are different, they discard everything and output FAIL.*

We point out that this protocol can be implemented by LOCC. In step 1, both Alice and Bob apply a scrambling permutation to their state. It is easy to verify that the mapping in Equation 11 is a permutation and thus is possible to realize quantum-mechanically. Next, if the scrambling permutation is efficient, there exists a polynomial-size quantum circuit that implements it [L01]. In step 2, Fourier Operators and Inverse Fourier Operators are applied by Alice and Bob, respectively. Fourier Operators exist for every N and when N is a power of 2, there exists an efficient implementation of both the Fourier Operators and Inverse Fourier Operators. Also, in the case N is a power of 2, there exists a very efficient algorithm for performing Hadamard operators. Therefore we have:

Claim 2 *The simple scrambling protocol can be implemented by LOCC. Furthermore, if the scrambling permutation used in the protocol is efficient and L is power of 2, the protocol can be efficiently implemented.*

C.3 The Analysis of the Simple Scrambling Protocol

Now we prove a lemma that the Simple Scrambling protocol is deterministically conditionally successful for input states that are *pure states* in the diagonal subspace.

Lemma 4 *If the input state to a Simple Scrambling protocol is a pure state in the diagonal subspace, then this protocol is deterministically conditionally successful with parameter $\langle N, K, WK, \epsilon, \frac{2W}{N}\epsilon, \epsilon \rangle$ for $\epsilon < 1/2$.*

Intuitively, this lemma is true because the Scrambling Permutation “shuffles” the coefficients of $|\phi\rangle$ very “evenly”. Then the Fourier operator (or the Hadamard operator) “mixes” all the coefficients together. Therefore when the protocol doesn’t fail, the coefficients of the output state are much more “smooth” than that of $|\phi\rangle$.

Proof: We write the input state $|\phi\rangle$ as

$$|\phi\rangle = \sum_{x \in X} \alpha_x |x\rangle^A |x\rangle^B \quad (12)$$

and we have that

$$\sum_{x \in X} |\alpha_x|^2 = 1$$

We denote $\sum_{x \in X} \alpha_x$ by D . Then we have

$$1 - \epsilon = |\langle \phi | \Psi_N \rangle|^2 = \frac{1}{N} \cdot \left| \sum_{x \in X} \alpha_x \right|^2 = \frac{|D|^2}{N} \quad (13)$$

We will go through the protocol and keep track of the state.

1. The initial state for Alice and Bob is

$$|\psi_1\rangle = |\phi\rangle \otimes \Psi_K = \frac{1}{\sqrt{K}} \sum_{x \in X} \sum_{y \in Y} \alpha_x |x \circ y\rangle^A |x \circ y\rangle^B \quad (14)$$

2. After applying the scrambling permutation, the state becomes

$$|\psi_2\rangle = \frac{1}{\sqrt{K}} \sum_{x \in X} \sum_{y \in Y} \alpha_x \cdot |g_y(x) \circ h_y(x) \circ y\rangle^A \cdot |g_y(x) \circ h_y(x) \circ y\rangle^B \quad (15)$$

3. After the Fourier and Inverse Fourier operators, the state is

$$|\psi_3\rangle = \frac{1}{L\sqrt{K}} \sum_{x \in X} \sum_{y \in Y} \sum_{g_A \in G} \sum_{g_B \in G} \omega^{g_y(x) \cdot (g_B - g_A)} \cdot \alpha_x \cdot |g_A \circ h_y(x) \circ y\rangle^A \cdot |g_B \circ h_y(x) \circ y\rangle^B \quad (16)$$

Alternatively, if L is a power of 2, and Hadamard operators are used instead of Fourier and Inverse Fourier operators, the state is

$$|\psi'_3\rangle = \frac{1}{L\sqrt{K}} \sum_{x \in X} \sum_{y \in Y} \sum_{g_A \in G} \sum_{g_B \in G} (-1)^{g_y(x) \cdot (g_A \oplus g_B)} \cdot \alpha_x \cdot |g_A \circ h_y(x) \circ y\rangle^A \cdot |g_B \circ h_y(x) \circ y\rangle^B \quad (17)$$

In either cases, if Alice and Bob both measure their qubits and they both obtain the result g , the state becomes

$$|\psi_{4,g}\rangle = \frac{\Delta}{L\sqrt{K}} \sum_{x \in X} \sum_{y \in Y} \alpha_x \cdot |g \circ h_y(x) \circ y\rangle^A \cdot |g \circ h_y(x) \circ y\rangle^B \quad (18)$$

where Δ is a normalization factor. Notice that if Alice and Bob both discard the qubits $|g\rangle^A$ and $|g\rangle^B$ (which are disentangled from the rest), the resultant state is the same for different $|g\rangle$'s:

$$|\psi_5\rangle = \frac{\Delta}{L\sqrt{K}} \sum_{x \in X} \sum_{y \in Y} \alpha_x \cdot |h_y(x) \circ y\rangle^A \cdot |h_y(x) \circ y\rangle^B \quad (19)$$

Now let's compute Δ .

To normalize $|\psi_5\rangle$, we can re-group the terms and re-write it as

$$|\psi_5\rangle = \frac{\Delta}{L\sqrt{K}} \sum_{u \in H} \sum_{y \in Y} \left(\sum_{h_y(x)=u} \alpha_x \right) \cdot |u \circ y\rangle^A \cdot |u \circ y\rangle^B \quad (20)$$

Therefore we should have

$$\frac{\Delta^2}{L^2 K} \sum_{u \in H} \sum_{y \in Y} \left| \sum_{h_y(x)=u} \alpha_x \right|^2 = 1$$

Furthermore, we have

$$\begin{aligned} \sum_{u \in H} \sum_{y \in Y} \left| \sum_{h_y(x)=u} \alpha_x \right|^2 &= \sum_{y \in Y} \sum_{u \in H} \left| \sum_{h_y(x)=u} \alpha_x \right|^2 \\ &= \sum_{y \in Y} \sum_{x \in X} |\alpha_x|^2 + \sum_{y \in Y} \sum_{x_1 \neq x_2, h_y(x_1)=h_y(x_2)} (\alpha_{x_1} \bar{\alpha}_{x_2} + \bar{\alpha}_{x_1} \alpha_{x_2}) \\ &= \sum_{y \in Y} 1 + \sum_{x_1 \neq x_2} \sum_{y \in Y: h_y(x_1)=h_y(x_2)} (\alpha_{x_1} \bar{\alpha}_{x_2} + \bar{\alpha}_{x_1} \alpha_{x_2}) \\ &= K + \sum_{x_1 \neq x_2} pK(\alpha_{x_1} \bar{\alpha}_{x_2} + \bar{\alpha}_{x_1} \alpha_{x_2}) \\ &= K + pK \left(\left| \sum_{x \in X} \alpha_x \right|^2 - \sum_{x \in X} |\alpha_x|^2 \right) \\ &= K[1 + p(|D|^2 - 1)] \end{aligned}$$

and thus

$$\begin{aligned} \Delta^2 &= \frac{L^2 K}{K[1 + p(|D|^2 - 1)]} \\ &= \frac{L^2}{1 + p(|D|^2 - 1)} \\ &= \frac{L^2}{1 + \frac{L-1}{N-1}(N-1 - N\epsilon)} \\ &= \frac{L}{1 - \epsilon \cdot \frac{N(L-1)}{L(N-1)}} \end{aligned}$$

Notice Δ^2 is the probability that Alice and Bob both obtain $|g\rangle$ for their measurement. There are L possible $|g\rangle$'s that Alice and Bob can obtain. So the probability that Alice and Bob obtain the same result is

$$\text{Prob [Alice and Bob obtain the same result]} = \frac{L}{\Delta^2} = 1 - \epsilon \cdot \frac{N(L-1)}{L(N-1)} \geq 1 - \epsilon$$

And the fidelity of $|\psi_5\rangle$ is

$$\begin{aligned}
F(|\psi_5\rangle\langle\psi_5|) &= |\langle\psi_5|\Psi_{WK}\rangle|^2 \\
&= \left| \frac{1}{\sqrt{WK}} \cdot \frac{\Delta}{L\sqrt{K}} \sum_{u \in H} \sum_{y \in Y} \left(\sum_{h_y(x)=u} \alpha_x \right) \right|^2 \\
&= \frac{\Delta^2}{L^2 K^2 W} \left| \sum_{u \in H} \sum_{y \in Y} \sum_{h_y(x)=u} \alpha_x \right|^2 \\
&= \frac{\Delta^2}{L^2 K^2 W} \left| \sum_{x \in X} \sum_{y \in Y} \alpha_x \right|^2 \\
&= \frac{\Delta^2}{L^2 K^2 W} \cdot |KD|^2 \\
&= \frac{(1-\epsilon) \cdot \Delta^2}{L} \\
&= \frac{1-\epsilon}{1-\epsilon \cdot \frac{N(L-1)}{L(N-1)}} \\
&= 1 - \epsilon \cdot \frac{N-L}{L(N-1)} \cdot \frac{1}{1-\epsilon \cdot \frac{N(L-1)}{L(N-1)}} \\
&\geq 1 - 2\epsilon \cdot \frac{N-L}{L(N-1)} \\
&= 1 - 2\epsilon \cdot \frac{W-1}{N-1} \\
&\geq 1 - \frac{2W}{N}\epsilon
\end{aligned}$$

■

Therefore, if the input state $|\phi\rangle$ has a sufficiently high fidelity, then with high probability the Simple Scrambling protocol will succeed, and the resultant state, which is also a pure state, can have a much higher fidelity.

Next, we prove that the Simple Scrambling protocol works without modification for mixed states in Diagonal Subspaces, with exactly the same parameters.

Lemma 5 *If the input state to a Simple Scrambling protocol is a mixed state in the diagonal subspace, then this protocol is deterministically conditionally successful with parameter $\langle N, K, WK, \epsilon, \frac{2W}{N}\epsilon, \epsilon \rangle$ for $\epsilon < 1/2$.*

Proof: We write the mixed state as an ensemble: $\{p_i, |\phi_i\rangle\}_{i=1,2,\dots,s}$. We use $1-\epsilon_i$ to denote the fidelity of pure state ϕ_i . Then we have $\epsilon = \sum_i p_i \cdot \epsilon_i$ by the linearity of fidelity.

As in the proof to Lemma 4, the protocol will succeed with probability $1 - \epsilon_i \cdot \frac{N(L-1)}{L(N-1)}$ for state $|\phi_i\rangle$. So the overall probability that the protocol doesn't fail is

$$\begin{aligned}
\text{Prob} [\mathcal{P}(|\phi_i\rangle\langle\phi_i|) = \text{FAIL}] &= \sum_i p_i \cdot \epsilon_i \cdot \frac{N(L-1)}{L(N-1)} \\
&= \frac{N(L-1)}{L(N-1)} \cdot \sum_i p_i \cdot \epsilon_i
\end{aligned}$$

$$\begin{aligned}
&= \frac{N(L-1)}{L(N-1)} \cdot \epsilon \\
&\leq \epsilon
\end{aligned}$$

If we use Q_i to denote the fidelity of the output of the protocol on state $|\phi_i\rangle$ conditioned on that it doesn't fail, then the overall fidelity of the output if the protocol doesn't fail is:

$$\begin{aligned}
Q &= \frac{\sum_i Q_i \cdot p_i \cdot \text{Prob}[\mathcal{P}(|\phi_i\rangle\langle\phi_i|) = \text{FAIL}]}{\sum_i p_i \cdot \text{Prob}[\mathcal{P}(|\phi_i\rangle\langle\phi_i|) = \text{FAIL}]} \\
&= \frac{\sum_i \frac{1-\epsilon_i}{1-\epsilon_i \cdot \frac{N(L-1)}{L(N-1)}} \cdot p_i \cdot \left[1 - \epsilon_i \cdot \frac{N(L-1)}{L(N-1)}\right]}{\sum_i p_i \cdot \left[1 - \epsilon_i \cdot \frac{N(L-1)}{L(N-1)}\right]} \\
&= \frac{\sum_i (1 - \epsilon_i) \cdot p_i}{\sum_i \left(1 - \frac{N(L-1)}{L(N-1)} \cdot \epsilon_i\right) \cdot p_i} \\
&= \frac{1 - \epsilon}{1 - \epsilon \cdot \frac{N(L-1)}{L(N-1)}} \\
&\geq 1 - \frac{2W}{N} \epsilon
\end{aligned}$$

So the Simple Scrambling protocol is deterministically conditionally successful even for mixed states in the diagonal subspace. ■

Now we are ready to prove Theorem 2.

Proof: [Proof to Theorem 2] We simply combine Theorem 4 and Lemma 5. ■

D Toward the Diagonal Subspace: The Hash and Compare Protocol

In this section, we present the construction of the Hash and Compare protocol. With high probability, this protocol converts any state of reasonably high fidelity into a state that is “almost completely” in the diagonal subspace. Therefore, if we combine this protocol with the Simple Scrambling protocol, we obtain a GEPP that is probabilistically conditionally successful for arbitrary states.

Before describing the actual protocol, we give some motivations and intuitions behind it. Suppose Alice and Bob share a state of fidelity at least $1 - \epsilon$. For simplicity, we assume that the state is a pure state, and we will show how to extend our result to mixed states later. We write the input state as $|\phi\rangle$. In this situation, the Simple Scrambling protocol doesn't work anymore. Essentially what this protocol does is to “shuffle” and “mix” the coefficients in the diagonal subspace in a very “even” way to increase the fidelity. The Scrambling Permutation guarantees that coefficients in the diagonal subspace will be mixed “evenly”. However it gives no guarantee for coefficients outside this subspace. Nevertheless, it is worth noting that the maximally entangled state, Ψ_N , is completely in the diagonal subspace. So if $|\phi\rangle$ is close to Ψ_N , then a large “fraction” of $|\phi\rangle$ must lie in the diagonal subspace.

We write

$$|\phi\rangle = \alpha \cdot |\phi_{\parallel}\rangle + \beta \cdot |\phi_{\perp}\rangle \tag{21}$$

where $|\phi_{\parallel}\rangle$ is a vector in the diagonal subspace $\mathcal{H}^{\mathcal{D}}$ and $|\phi_{\perp}\rangle$ is a vector orthogonal to $\mathcal{H}^{\mathcal{D}}$ subspace. Both vectors are normalized, and thus we have $|\alpha|^2 + |\beta|^2 = 1$. Obviously we have $\langle\phi_{\perp}|\Psi_N\rangle = 0$ and thus $|\alpha|^2 \geq 1 - \epsilon$.

The Simple Scrambling protocol works well for state $|\phi_{\parallel}\rangle$, but does not work for state $|\phi_{\perp}\rangle$. So if we can first “eliminate” $|\phi_{\perp}\rangle$, or at least decrease its coefficient from β to a much smaller one, we can use the Simple Scrambling protocol to obtain a state with high fidelity. The Hash and Compare protocol does exactly this.

Construction 3 (Hash and Compare) *The input to the protocol is a state ρ in the subspace $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$. The protocol also has an auxiliary input Ψ_S , where $S = 2^s$ is a power of 2. The output of the protocol is a state σ in $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$. The steps are:*

1. *Alice randomly generates s numbers $r_0, r_1, \dots, r_{s-1} \in [N]$ and introduces s ancillary qubits, $|b_0\rangle, |b_1\rangle, \dots, |b_{s-1}\rangle$, all initialized to $|0\rangle$.*
2. *Alice performs s unitary operations:*

$$|x\rangle|y_j\rangle \longrightarrow |x\rangle|y_j \oplus (x \bullet r_j)\rangle$$

She uses the qubits from state ρ as x , and the ancillary qubit $|b_j\rangle$ as y_j , for $j = 0, 1, \dots, s-1$.

3. *Alice send $r_0, r_1, \dots, r_{s-1}$ to Bob.*
4. *Alice and Bob engage in s teleportation protocols. They use the shared state Ψ_S as s EPR pairs, to teleport the s ancillary qubits $|b_0\rangle^A, |b_1\rangle^A, \dots, |b_{s-1}\rangle^A$ from Alice to Bob. Then Alice discards all her ancillary qubits. Bob obtains the qubits $|b_0\rangle^B, |b_1\rangle^B, \dots, |b_{s-1}\rangle^B$.*
5. *Bob performs s unitary operations (the same operations as Alice did):*

$$|x\rangle|y_j\rangle \longrightarrow |x\rangle|y_j \oplus (x \bullet r_j)\rangle$$

He uses the qubits from state $|\phi\rangle$ as x , and qubit $|b_j\rangle^B$ as y_j , for $j = 0, 1, \dots, s-1$.

6. *Bob measures all his ancillary bits $|b_0\rangle^B, |b_1\rangle^B, \dots, |b_{s-1}\rangle^B$.*
7. *If all the results of the measurements are 0, Bob discards all the ancillary qubits. Then Alice and Bob output the remaining state, which is in Hilbert space $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$.*
8. *If not all the results of the measurements are 0, Alice and Bob discard everything and output FAIL.*

We point out that the Hash and Compare protocol can be efficiently implemented.

Now we prove that the Hash and Compare protocol will bring the input state $|\phi\rangle$ to another state that is “almost” in the diagonal subspace.

First, we extend the definition of fidelity. We define the fidelity between a pure state $|\varphi\rangle$ and a linear subspace L to be the square of the length of the the projection of $|\varphi\rangle$ on L . Alternatively, we have

$$F(|\varphi\rangle, L) = \max_{|\psi\rangle \in L} |\langle \varphi | \psi \rangle|^2 \quad (22)$$

Now we state and prove our lemma about the Hash and Compare protocol.

Lemma 6 *Let state $|\phi\rangle$ be a pure state of fidelity at least $1 - \epsilon$, where $\epsilon < 1/2$. If $|\phi\rangle$ is the input state to the Hash and Compare protocols, then the probability this protocol outputs FAIL is at most ϵ . Given that the protocol doesn't fail, we use $|\psi\rangle$ to denote the output state, which is a pure state. We have $F(|\psi\rangle\langle\psi|) \geq 1 - \epsilon$, and*

$$\text{Prob} [F(|\psi\rangle, \mathcal{H}^D) \geq 1 - \frac{2}{\sqrt{S}}\epsilon] \geq 1 - \frac{1}{\sqrt{S}}$$

Proof: We write the state $|\phi\rangle$ as

$$|\phi\rangle = \sum_{x_A \in X} \sum_{x_B \in X} \alpha_{x_A, x_B} |x_A\rangle^A |x_B\rangle^B \quad (23)$$

and we have

$$\sum_{x_A \in X} \sum_{x_B \in X} |\alpha_{x_A, x_B}|^2 = 1$$

Comparing this to Equation 21, we conclude that

$$\begin{aligned} |\alpha|^2 &= \sum_{x \in X} |\alpha_{x,x}|^2 \\ |\beta|^2 &= \sum_{x_A \neq x_B} |\alpha_{x_A, x_B}|^2 \end{aligned}$$

We go through the protocol:

1. The initial state for Alice and Bob, excluding the auxiliary input Ψ_T is:

$$|\phi_1\rangle = \sum_{x_A \in X} \sum_{x_B \in X} \alpha_{x_A, x_B} |x_A\rangle^A |x_B\rangle^B$$

2. After Alice introduces her ancillary qubits and done with the t unitary operations, the state is:

$$|\phi_2\rangle = \sum_{x_A \in X} \sum_{x_B \in X} \alpha_{x_A, x_B} |x_A\rangle^A |x_A \bullet r_0\rangle^A |x_A \bullet r_1\rangle^A \cdots |x_A \bullet r_{s-1}\rangle^A |x_B\rangle^B \quad (24)$$

as we can see, the ancillary qubits are entangled with the qubits from $|\phi\rangle$.

3. After the teleportation, Alice's ancillary qubits becomes disentangled from the qubits of $|\phi\rangle$, and after discarding all the ancillary qubits of Alice, the state becomes

$$|\phi_3\rangle = \sum_{x_A \in X} \sum_{x_B \in X} \alpha_{x_A, x_B} |x_A\rangle^A |x_B\rangle^B |x_A \bullet r_0\rangle^B |x_A \bullet r_1\rangle^B \cdots |x_A \bullet r_{s-1}\rangle^B \quad (25)$$

4. After Bob has done with his unitary operations, the state becomes

$$|\phi_4\rangle = \sum_{x_A \in X} \sum_{x_B \in X} \alpha_{x_A, x_B} |x_A\rangle^A |x_B\rangle^B |(x_A \oplus x_B) \bullet r_0\rangle^B |(x_A \oplus x_B) \bullet r_1\rangle^B \cdots |(x_A \oplus x_B) \bullet r_{s-1}\rangle^B \quad (26)$$

5. Next, Bob measures all his ancillary qubits. Now it should be clear that if the state Alice and Bob start with, $|\phi\rangle$, is indeed in the diagonal subspace, then all the measurements will yield 0 with probability one, since we have $x_A = x_B$ for all non-zero α_{x_A, x_B} 's.

Now that $|\phi\rangle$ is not in the diagonal subspace, but it is close. Thus intuitively, Bob should have a high probability getting all 0's in his measurement.

We do a more formal analysis: we denote by Z the subset of $[N]$ whose elements have inner product 0 with all $r_0, r_1, \dots, r_{s-1}$:

$$Z = \{x \mid x \in [N], x \bullet r_j = 0, j = 0, 1, \dots, s-1\}$$

We group all the terms in Equation 26 into 3 parts:

$$|\phi_4\rangle = \lambda_0 \cdot |\psi_0\rangle + \lambda_1 \cdot |\psi_1\rangle + \lambda_2 \cdot |\psi_2\rangle$$

where

$$\lambda_0 \cdot |\psi_0\rangle = \sum_{x \in X} \alpha_{x,x} \cdot |x\rangle^A |x\rangle^B |0\rangle^B \cdots |0\rangle^B$$

$$\lambda_1 \cdot |\psi_1\rangle = \sum_{x_A \neq x_B, x_A \oplus x_B \in Z} \alpha_{x_A, x_B} \cdot |x_A\rangle^A |x_B\rangle^B |0\rangle^B \cdots |0\rangle^B$$

$$\lambda_2 \cdot |\psi_2\rangle = \sum_{x_A \neq x_B, x_A \oplus x_B \notin Z} \alpha_{x_A, x_B} \cdot |x_A\rangle^A |x_B\rangle^B |(x_A \oplus x_B) \bullet r_0\rangle^B |(x_A \oplus x_B) \bullet r_1\rangle^B \cdots |(x_A \oplus x_B) \bullet r_{s-1}\rangle^B$$

Both $|\psi_0\rangle$ and $|\psi_1\rangle$ have all 0's in the ancillary qubits of Bob, while $|\psi_2\rangle$ doesn't. All these 3 states, $|\psi_0\rangle, |\psi_1\rangle$ and $|\psi_2\rangle$ are orthogonal to each other.

We again write

$$|\phi\rangle = \alpha \cdot |\phi_{\parallel}\rangle + \beta \cdot |\phi_{\perp}\rangle$$

and we notice that $\lambda_0 = \alpha$, and $|\psi_0\rangle = |\phi_{\parallel}\rangle \otimes |Z_T\rangle^B$

Therefore the probability that Bob obtains all-zero in the measurement is at least $|\lambda_0|^2 = |\alpha|^2 \geq 1 - \epsilon$.

After the measurement, and if its result is indeed all-zero, the state will become

$$|\psi\rangle = \frac{1}{\sqrt{|\lambda_0|^2 + |\lambda_1|^2}} \cdot (\lambda_0 |\psi_0\rangle + \lambda_1 |\psi_1\rangle) \quad (27)$$

where $|\psi_0\rangle$ is in the diagonal subspace $\mathcal{H}^D$ and $|\psi_1\rangle$ is orthogonal to the $\mathcal{H}^D$. The fidelity of $|\psi\rangle$ and $\mathcal{H}^D$ is $\frac{|\lambda_0|}{\sqrt{|\lambda_0|^2 + |\lambda_1|^2}}$.

Now we can prove that the fidelity of $|\psi\rangle$ is at least $1 - \epsilon$:

$$\begin{aligned} \langle \psi | \Psi_N \rangle &= \frac{\lambda_0}{\sqrt{|\lambda_0|^2 + |\lambda_1|^2}} \langle \psi_0 | \Psi_N \rangle + \frac{\lambda_1}{\sqrt{|\lambda_0|^2 + |\lambda_1|^2}} \langle \psi_1 | \Psi_N \rangle \\ &= \frac{\langle \lambda_0 \psi_0 | \Psi_N \rangle}{\sqrt{|\lambda_0|^2 + |\lambda_1|^2}} \\ &= \frac{1}{\sqrt{|\lambda_0|^2 + |\lambda_1|^2}} \cdot \frac{|\sum_{x \in X} \alpha_{x,x}|}{\sqrt{N}} \\ &= \frac{\langle \phi | \Psi_N \rangle}{\sqrt{|\lambda_0|^2 + |\lambda_1|^2}} \\ &\geq \langle \phi | \Psi_N \rangle \geq 1 - \epsilon \end{aligned}$$

Essentially, the hash and compare protocol leaves the coefficients in diagonal subspace untouched, and eliminates part of the “off-diagonal” coefficients. Therefore, after the re-normalization, the coefficients in the diagonal subspace will not decrease, and thus the fidelity of the output state is at least $1 - \epsilon$.

Now we estimate the magnitude of λ_1 : we have

$$|\lambda_1|^2 = \sum_{x_A \neq x_B, x_A \oplus x_B \in Z} |\alpha_{x_A, x_B}|^2$$

Notice that λ_1 is actually a random variable since the $r_0, r_1, \dots, r_{t-1}$ are randomly chosen by Alice. Notice that each pair $x_A \neq x_B$, we have

$$\text{Prob}_r[(x_A \oplus x_B) \bullet r = 0] = 1/2$$

and thus for random $r_0, r_1, \dots, r_{s-1}$, the probability that all $(x_A \oplus x_B) \bullet r_j$ results in 0 for $j = 0, 1, \dots, s-1$, is $1/2^s$.

In other words, the expected value of $|\lambda_1|^2$ is

$$\begin{aligned} E[|\lambda_1|^2] &= E\left[\sum_{x_A \neq x_B, x_A \oplus x_B \in Z} |\alpha_{x_A, x_B}|^2\right] \\ &= \sum_{x_A \neq x_B} \text{Prob}_{r_0, r_1, \dots, r_{s-1}}[x_A \oplus x_B \in Z] \cdot |\alpha_{x_A, x_B}|^2 \\ &= \frac{1}{2^s} \sum_{x_A \neq x_B} |\alpha_{x_A, x_B}|^2 \\ &\leq \frac{\epsilon}{S} \end{aligned}$$

and thus by Markov Inequality, we have

$$\text{Prob}[|\lambda_1|^2 \leq \frac{\epsilon}{\sqrt{S}}] \leq \frac{1}{\sqrt{S}}$$

Therefore, with probability at least $1 - \frac{1}{\sqrt{S}}$, we have $|\lambda_1|^2 \leq \frac{\epsilon}{\sqrt{S}}$. In that case, the fidelity of $|\psi\rangle$ and the diagonal subspace is

$$\begin{aligned} F(|\psi\rangle, \mathcal{H}^{\mathcal{D}}) &= \frac{|\lambda_0|^2}{|\lambda_0|^2 + |\lambda_1|^2} \\ &\geq \frac{1 - \epsilon}{1 - \epsilon + \frac{\epsilon}{\sqrt{S}}} \\ &= 1 - \frac{\epsilon}{\sqrt{S} \cdot (1 - \epsilon + \frac{\epsilon}{\sqrt{S}})} \\ &\geq 1 - \frac{2\epsilon}{\sqrt{S}} \end{aligned}$$

when $\epsilon < 1/2$. ■

Now, we can put everything together: for a general state ρ , we first apply the Hash and Compare protocol to ρ to make it “almost completely in” the diagonal subspace $\mathcal{H}^{\mathcal{D}}$. Then we apply the Simple Scrambling protocol to enhance the fidelity. We describe the complete protocol in more details:

Construction 4 (Complete Scrambling Protocol) *The Complete Scrambling protocol is parameterized by a quintuple: $\langle N, K, W, L, S \rangle$, such that there exists a Scrambling Permutation pair $\langle g_y(x), h_y(x) \rangle$ of parameter $\langle N, K, W, L \rangle$, where S is a power of 2. The input to the protocol is a (mixed) state ρ in space $\mathcal{H}_N^A \otimes \mathcal{H}_N^B$. The protocol also has an auxiliary input Ψ_T , where $T = S \cdot K$. We can also write the auxiliary input Ψ_T as $\Psi_S \otimes \Psi_K$. The steps are:*

1. *Alice and Bob engage in the Hash and Compare protocol, using the input state ρ as the input, and part of the auxiliary input, Ψ_S as the auxiliary input.*
2. *If the Hash and Compare protocol fails, Alice and Bob output FAIL and terminate.*
3. *If the Hash and Compare protocol succeeds, it will output a state σ . Alice and Bob then engage in the Simple Scrambling protocol, using σ as the input and the other part of the auxiliary input, Ψ_K as the auxiliary input.*
4. *If the Simple Scrambling protocol fails, Alice and Bob output FAIL and terminate.*
5. *If the Simple Scrambling protocol succeeds, a state τ will be output, and Alice and Bob output τ .*

It is obvious that the complete scrambling protocol can be realized quantum-mechanically, and if the scrambling permutation used in the protocol is an efficient one, and L is a power of 2, the protocol can be realized efficiently.

Lemma 7 *The Complete Scrambling protocol is a probabilistic conditional successful GEPP with parameter $\langle N, SK, WK, \epsilon, (\frac{4M}{N} + \frac{4}{\sqrt{S}})\epsilon, 2\epsilon + \sqrt{\frac{2\epsilon}{\sqrt{S}}}, \frac{1}{\sqrt{S}} \rangle$. If the Simple Scrambling protocol used inside the complete protocol is efficient, then so is the complete protocol.*

Proof: To prove this lemma we need some claims about fidelity:

Claim 3 (Monotonicity) For any (mixed) states ρ and σ and any quantum operator $\mathcal{E}$ (not necessarily unitary), we have

$$F(\mathcal{E}(\rho), \mathcal{E}(\sigma)) \geq F(\rho, \sigma) \quad (28)$$

■

It is a well-known result [NC00].

Claim 4 (Triangle Inequality) For any 3 pure states $|A\rangle$, $|B\rangle$ and $|C\rangle$ in the same Hilbert space $\mathcal{H}$ such that $F(|A\rangle, |B\rangle) = 1 - \epsilon$ and $F(|A\rangle, |C\rangle) = 1 - \delta$, where both ϵ and δ are real numbers between 0 and 1/2. then we have

$$F(|B\rangle, |C\rangle) \geq 1 - 2(\epsilon + \delta)$$

Claim 5 (Relationship to Statistical Distance) Let ρ and σ be 2 mixed states in the Hilbert space $\mathcal{H}$ such that $F(\rho, \sigma) = 1 - \epsilon$. Let $\mathcal{E}$ be an arbitrary quantum operation over $\mathcal{H}$ that ends with a measurement. We use M_ρ and M_σ to denote the random variables describing the outcomes of the measurement of $\mathcal{E}$ on input ρ and σ , respectively. Then the statistical distance between M_ρ and M_σ is at most $\sqrt{\epsilon}$.

We prove Claim 4 and Claim 5 in Appendix F.

We first consider the case that the input state is a pure state $|\phi\rangle$. By Lemma 6, with probability at least $1 - \epsilon$, the Hash and Compare protocol will succeed. In the case it succeeds, the output state $|\psi\rangle$ will have a fidelity at least $(1 - \frac{2\epsilon}{\sqrt{S}})$ with the diagonal subspace $\mathcal{H}^{\mathcal{D}}$ with probability $1 - \frac{1}{\sqrt{S}}$. We define a “good event” to be the event that $|\psi\rangle$ has fidelity at least $(1 - \frac{2\epsilon}{\sqrt{S}})$ with $\mathcal{H}^{\mathcal{D}}$. Then the probability a good event happens is at least $1 - \frac{1}{\sqrt{S}}$. We focus on the good events. We write the normalized projection of $|\psi\rangle$ to $\mathcal{H}^{\mathcal{D}}$ as $|\psi_{\mathcal{D}}\rangle$. So we have

$$F(|\psi\rangle, |\psi_{\mathcal{D}}\rangle) \geq 1 - \frac{2\epsilon}{\sqrt{S}}$$

In other words, the fidelity of state $|\psi\rangle$ and the state $|\psi_{\mathcal{D}}\rangle$ is at least $1 - \frac{2\epsilon}{\sqrt{S}}$. If Alice and Bob, instead of feeding $|\psi\rangle$, had fed $|\psi_{\mathcal{D}}\rangle$ into the Simple Scrambling protocol, they would have succeeded with probability at least $1 - \epsilon$, and output a pure state $|\psi_{\mathcal{D}}^E\rangle$ of fidelity at least $1 - \frac{2W}{N}\epsilon$. However, since Alice and Bob don’t feed $|\psi_{\mathcal{D}}\rangle$ into the Simple Scrambling protocol, they don’t get $|\psi_{\mathcal{D}}^E\rangle$ back: rather they get a state $|\psi^E\rangle$ if they don’t fail⁴. By the monotonicity of fidelity, we have that

$$\langle \psi^E | \psi_{\mathcal{D}}^E \rangle \geq \langle \psi | \psi_{\mathcal{D}} \rangle \geq 1 - \frac{2\epsilon}{\sqrt{S}} \quad (29)$$

Combining Equation 29 with the fact that $F(|\psi_{\mathcal{D}}^E\rangle, |\Psi_{WK}\rangle) \geq 1 - \frac{2W}{N}\epsilon$, we have, by Claim 4,

$$F(|\psi^E\rangle, |\Psi_{WK}\rangle) \geq 1 - (\frac{4W}{N} + \frac{4}{\sqrt{S}})\epsilon$$

We denote by p the failing probability of the Simple Scrambling protocol on input $|\psi\rangle$, and $p_{\mathcal{D}}$ the failing probability on input $|\psi_{\mathcal{D}}\rangle$. Then we have, by Claim 5,

$$|p - p_{\mathcal{D}}| \leq \sqrt{\frac{2\epsilon}{\sqrt{S}}}$$

⁴It is easy to check that the Simple Scrambling protocol always outputs a pure state if the input state is pure.

Putting things together, we have: with probability at least $1 - 2\epsilon - \sqrt{\frac{2\epsilon}{\sqrt{S}}}$, the Complete Scrambling protocol succeeds. In the case it succeeds, it outputs a state $|\psi^E\rangle$ of fidelity at least $1 - (\frac{4W}{N} + \frac{4}{\sqrt{S}})\epsilon$ with probability at least $1 - \frac{1}{\sqrt{S}}$.

Next we consider the case that the input state is a mixed state ρ . We have $F(\rho) \geq 1 - \epsilon$. We write ρ as an ensemble $\{p_i, |\phi_i\rangle\}$. For each pure state $|\phi_i\rangle$, we assume that it has fidelity $1 - \epsilon_i$, and then by the linearity of fidelity, we have $\sum_i p_i \epsilon_i = \epsilon$. The analysis above works for each pure state $|\psi_i\rangle$: for each pure state $|\phi_i\rangle$, with probability at least $1 - 2\epsilon_i - \sqrt{\frac{2\epsilon_i}{\sqrt{S}}}$, the Complete Scrambling protocol succeeds. In the case it succeeds, it outputs a state $|\psi_i^E\rangle$ of fidelity at least $1 - (\frac{4W}{N} + \frac{4}{\sqrt{S}})\epsilon_i$ with probability at least $1 - \frac{1}{\sqrt{S}}$. The fidelity $1 - (\frac{4W}{N} + \frac{4}{\sqrt{S}})\epsilon_i$ is a linear function in ϵ_i , and $1 - 2\epsilon - \sqrt{\frac{2\epsilon}{\sqrt{S}}}$ is a convex function. So overall, the Complete Scrambling protocol succeeds with probability at least $1 - 2\epsilon - \sqrt{\frac{2\epsilon}{\sqrt{S}}}$. In the case it succeeds, it outputs a state $|\psi^E\rangle$ of fidelity at least $1 - (\frac{4W}{N} + \frac{4}{\sqrt{S}})\epsilon$ with probability at least $1 - \frac{1}{\sqrt{S}}$. ■

Now we are ready to prove Theorem 3.

Proof: [Proof to Theorem 3] We simply combine Theorem 4 and Lemma 7 and choose $S = 2^{2t}$. ■

E Constructions of Scrambling Permutations

We discuss various constructions of Scrambling Permutations.

For a binary string $S = s_1 s_2 \dots s_n$, we define the *left sub-string* and the *right sub-string* of the string S as follows:

$$\begin{aligned} \text{LEFT}(k, S) &= s_1 s_2 \dots s_k \\ \text{RIGHT}(k, S) &= s_{n-k+1} s_{n-k+2} \dots s_n \end{aligned}$$

Obviously we have

$$\text{LEFT}(k, S) \circ \text{RIGHT}(n - k, S) = S$$

The first construction is a very simple one, and it is very closely related to a construction of universal hash functions.

Construction 5 (Multiplication-table Scrambling Permutation) We work in GF_{2^n} , where each element is a polynomial of degree at most $n - 1$, and can be written as

$$a_0 + a_1 \cdot Z + \dots + a_{n-1} \cdot Z^{n-1}$$

We identify each element with an n -bit binary string in the most straight-forward way. We set $X = GF_{2^n}$ and $Y = GF_{2^n}^* = X \setminus \{\mathbf{0}\}$, where $\mathbf{0}$ is the additive identity in GF_{2^n} . We can pick an arbitrary l , such that $1 \leq l < n$. Then we let $G = \{0, 1\}^l$ and $H = \{0, 1\}^{n-l}$. The functions are:

$$\begin{aligned} g_y(x) &= \text{LEFT}(l, x \cdot y) \\ h_y(x) &= \text{RIGHT}(n - l, x \cdot y) \end{aligned}$$

and we have $N = 2^n$, $K = 2^n - 1$, $L = 2^l$, and $M = 2^{n-l}$.

Notice that a very common construction for universal hash functions over GF_{2^n} is $h_{y,z}(x) = x \cdot y + z$, and our construction can be viewed as a sub-family of this universal hash family, by setting $z = 0$. Our construction here is *not* a universal hash function family, but is more efficient.

Lemma 8 *The function pair given in Construction 5 is an efficient Scrambling Permutation pair.*

Proof: It is obvious that $\langle g_y(\cdot), h_y(\cdot) \rangle$ is a permutation, since

$$g_y(x) \circ h_y(x) = x \cdot y$$

is a permutation for $y \neq \mathbf{0}$.

Now let's prove that for any $x_1 \neq x_2$, $\text{Prob}_y[h_y(x_1) = h_y(x_2)]$ is always the same. This is actually not hard: we have $h_y(x_1) = h_y(x_2)$, iff

$$(x_1 - x_2) \cdot y = 0 \text{ mod } (Z^{n-l})$$

There are exactly 2^l elements in GF_N that are multiples of (Z^{n-l}) , and so there are exactly 2^l y 's that satisfy the equation. However, one such y is $\mathbf{0}$ and has to be excluded. So the probability is $p = (2^l - 1)/(2^n - 1) = (L - 1)/(N - 1)$. This is true for every pair $x_1 \neq x_2$.

Finally, both the permutation and its inverse can be implemented efficiently (only field multiplication and inversion are involved). So this scrambling permutation is efficient. ■

A word about efficiency: it is desirable for us to construct families of scrambling permutations of relatively small K and L , as compared M : In the Simple Scrambling protocol, where the Scrambling Permutation is used, N is the dimension of the input state that Alice and Bob try to purify, which is normally fixed; K is the dimension of maximally entangled state Alice and Bob invests; M is the “yield” of the protocol, or the dimension of the output; L is the dimension of the subspace Alice and Bob discard. So the Simple Scrambling protocol invests about $\log K$ perfect EPR pairs and discard about $\log L$ amount of entanglement. For the Multiplication-table construction, K is almost as large as N , which is a disadvantage since Alice and Bob has to invest as many perfect EPR pairs as the imperfect ones they try to purify. However, the L in this construction is fully adjustable, and it provides a nice trade-off between the yield Alice and Bob wish to obtain and the fidelity of the output (the greater L is, the less the yield is, and the higher fidelity the output has).

Below is another construction:

Construction 6 (Linear Function Scrambling Permutation) *We work in GF_{2^n} , and let $X = GF_{2^n} \times GF_{2^n}$. Therefore each element in X is represented by $\langle x_0, x_1 \rangle$. We let $Y = GF_{2^n} \cup \{\perp\}$, where $\perp$ is a special symbol.*

Both functions $g_y(\langle x_0, x_1 \rangle)$ and $h_y(\langle x_0, x_1 \rangle)$ output elements in GF_{2^n} and the actual functions are defined as follows:

$$\begin{aligned} g_y(\langle x_0, x_1 \rangle) &= \begin{cases} x_0 & \text{if } y \in GF_{2^n} \\ x_1 & \text{if } y = \perp \end{cases} \\ h_y(\langle x_0, x_1 \rangle) &= \begin{cases} x_0 \cdot y + x_1 & \text{if } y \in GF_{2^n} \\ x_0 & \text{if } y = \perp \end{cases} \end{aligned}$$

and we have $N = 2^{2n}$, $K = 2^n + 1$, $M = 2^n$, and $L = 2^n$.

Lemma 9 *The function pair given in Construction 6 is an efficient Scrambling Permutation pair.*

Proof: It is easy to verify that for any y , $g_y(\langle x_0, x_1 \rangle) \circ h_y(\langle x_0, x_1 \rangle)$ is a permutation.

Next we prove the scrambling property: for any pair of inputs $x = \langle x_0, x_1 \rangle$ and $x' = \langle x'_0, x'_1 \rangle$:

- If $x_0 \neq x'_0$, then the unique $y = (x_1 - x'_1) \cdot (x_0 - x'_0)^{-1}$ makes $h_y(\langle x_0, x_1 \rangle) = h_y(\langle x'_0, x'_1 \rangle)$.

- If $x_0 = x'_0$, then the unique $y = \perp$ makes $h_y(\langle x_0, x_1 \rangle) = h_y(\langle x'_0, x'_1 \rangle)$.

Finally, it is easy both the permutation and its can be computed efficiently, and thus the linear function construction is an efficient Scrambling Permutation pair. $\blacksquare$

In this construction, K is about the square root of N , which is much better than the Multiplication-table construction. However, L is fixed, and we don't have the flexibility as in the Multiplication-table construction. However, we can extend this construction to a class of Scrambling Permutations, and resolve the flexibility problem.

Construction 7 (Extended Linear Function Scrambling Permutation) We work in GF_{2^n} , and let $X = GF_{2^n}^d$, where d is an integer. Therefore each element in X is represented by a d -tuple $\langle x_0, x_1, \dots, x_{d-1} \rangle$. We let $Y = \bigcup_{k=0}^{d-1} GF_{2^n}^d$, where we define $GF_{2^n}^0 = \{\perp\}$.

The function $g_y(\langle x_0, x_1, \dots, x_{d-1} \rangle)$ outputs an element in GF_{2^n} and the function $h_y(\langle x_0, x_1, \dots, x_{d-1} \rangle)$ output a $(d-1)$ -tuple in GF_{2^n} : For any $y \in Y$, we write $y = \langle y_0, y_1, \dots, y_{k-1} \rangle$, where $0 \leq k < d$.

$$\begin{aligned} g_y(\langle x_0, x_1, \dots, x_{d-1} \rangle) &= x_k \\ h_y(\langle x_0, x_1, \dots, x_{d-1} \rangle) &= \langle x_0 + x_k \cdot y_0, x_1 + x_k \cdot y_1, \dots, x_{k-1} + x_k \cdot y_{k-1}, x_{k+1}, x_{k+2}, \dots, x_{d-1} \rangle \end{aligned}$$

and we have $N = 2^{dn}$, $K = \frac{2^{dn}-1}{2^n-1}$, $M = 2^{(d-1)n}$, and $L = 2^n$.

Here is a concrete example for $d = 4$:

y	$g_y(x)$	$h_y(x)$
$y = \perp$	x_0	x_1, x_2, x_3
$y = \langle y_0 \rangle$	x_1	$x_0 + x_1 \cdot y_0, x_2, x_3$
$y = \langle y_0, y_1 \rangle$	x_2	$x_0 + x_2 \cdot y_0, x_1 + x_2 \cdot y_1, x_3$
$y = \langle y_0, y_1, y_2 \rangle$	x_3	$x_0 + x_3 \cdot y_0, x_1 + x_3 \cdot y_1, x_2 + x_3 \cdot y_2$

Lemma 10 The function pair defined in Construction 7 is an efficient Scrambling Permutation pair.

Proof: The permutation property is obvious, and it is easy to see that both the permutation and its inverse can be computed efficiently.

Now the scrambling property: given any pair $x = \langle x_0, x_1, \dots, x_{d-1} \rangle$ and $x' = \langle x'_0, x'_1, \dots, x'_{d-1} \rangle$. we show that there is always a unique y such that $h_y(x) = h_y(x')$. We define k to be the largest index such that $x_k \neq x'_k$. Then for $y \in GF_{2^n}^l$,

1. If $l < k$, then the k -th entry in $h_y(x)$ is x_k , and it is different from the k -th entry in $h_y(x')$, which is x'_k ;
2. If $l = k$, we are effectively solving a linear system:

$$\begin{aligned} x_0 + x_k \cdot y_0 &= x'_0 + x'_k \cdot y_0 \\ x_1 + x_k \cdot y_1 &= x'_1 + x'_k \cdot y_1 \\ &\dots \\ x_{k-1} + x_k \cdot y_{k-1} &= x'_{k-1} + x'_k \cdot y_{k-1} \end{aligned}$$

and it has a unique solution

$$\begin{aligned} y_0 &= (x_0 - x'_0) \cdot (x_k - x'_k)^{-1} \\ y_1 &= (x_1 - x'_1) \cdot (x_k - x'_k)^{-1} \\ &\dots \\ y_{k-1} &= (x_{k-1} - x'_{k-1}) \cdot (x_k - x'_k)^{-1} \end{aligned}$$

3. If $l > k$, the k -th entry of x is $x_k + y_k \cdot x_{k+1}$, and it is different from the k -th entry of x' , which is $x'_k + y_k \cdot x_{k+1}$, since $x_k \neq x'_k$, while $x_{k+1} = x'_{k+1}$.

So there exists a unique $y \in Y$ such that $h_y(x) = h_y(x')$. ■

The extended linear function construction gives a class of Scrambling Permutations of different parameters: for a fixed N , we can pick a construction such that K is about $N^{(d-1)/d}$ and L is about $N^{1/d}$ for any integer d . When $d = 2$, the extended linear function construction becomes the linear function construction. So we get back some flexibility: not only in K , but also in L .

Of course, one question is: how good are our constructions in terms of the size of K and L as compared to N ? We hope K and L are as small as possible, and how small can they be? We have the following theorem which essentially says that the Extended Linear Function construction is optimal in terms of the size of K and L .

Theorem 6 *Let $\langle g_y(x), h_y(x) \rangle$ be a scrambling permutation pairs of parameter $\langle N, K, M, L \rangle$. We have $N \leq KL$.*

Proof: First, by Theorem 5, we know that the collision probability $p = (L - 1)/(N - 1)$.

Recall that p is the probability that a random $y \in Y$ satisfies $h_y(x_1) = h_y(x_2)$, and thus it is at least $1/K$. Therefore we have

$$\frac{1}{K} \leq \frac{L - 1}{N - 1}$$

or

$$K \geq \frac{N - 1}{L - 1} \geq \frac{N}{L}$$
■

It is easy to see that the Extended Linear Function construction achieves this bound asymptotically. We summarize the 3 constructions in the following table, which essentially proves Theorem 4.

Construction	N	K	M	L	Comments
Multiplication-table	2^n	$2^n - 1$	2^{n-l}	2^l	Fully adjustable L , not optimal
Linear Function	2^{2n}	$2^n + 1$	2^n	2^n	Minimal K among all constructions, optimal, inflexible
Extended Linear Function	2^{dn}	$\frac{2^{dn}-1}{2^n-1}$	$2^{(d-1)n}$	2^n	Optimal, flexible K and L

F Proofs to Two Claims About Fidelity

We give the proofs to 2 claims about fidelity that are used in this paper.

Proof: [Proof to Claim 4] Notice that $|A\rangle$, $|B\rangle$ and $|C\rangle$ are vectors in $\mathcal{H}$. We denote the angle between $|A\rangle$ and $|B\rangle$ by θ_{AB} , and define θ_{BC} , and θ_{CA} accordingly. Then it is easy to see (by the triangle inequality), that $\theta_{BC} \leq \theta_{AB} + \theta_{AC}$. It is also easy to see that $\cos \theta_{AB} = \langle A | B \rangle = \sqrt{1 - \epsilon}$ and $\cos \theta_{AC} = \langle A | C \rangle = \sqrt{1 - \delta}$. Therefore, we have

$$\begin{aligned}
\langle B | C \rangle &= \cos \theta_{BC} \\
&\geq \cos(\theta_{AB} + \theta_{AC}) \\
&= \cos \theta_{AB} \cos \theta_{AC} - \sin \theta_{AB} \sin \theta_{AC} \\
&= \sqrt{(1 - \epsilon)(1 - \delta)} - \sqrt{\epsilon\delta} \\
&\geq \sqrt{1 - 2(\epsilon + \delta)}
\end{aligned}$$

where the last step is a simple algebraic deduction. ■

Proof: [Proof to Claim 5] We use $D(\rho, \sigma)$ to denote the trace distance between ρ and σ , and we have[NC00]

$$D(\rho, \sigma) \leq \sqrt{1 - F(\rho, \sigma)} = \sqrt{\epsilon}$$

However the statistical distance between M_ρ and M_σ is bounded by $D(\rho, \sigma)$, which is bounded by $\sqrt{\epsilon}$.
